Abstract

Hydrogen ions (H+) and hydroxide ions (OH-) are regarded as ideal charge carriers for rechargeable batteries thanks to their small size, high ion mobility, low cost, and wide flexibility compared to the metal ions. However, the implementation of storage of both H+ and OH- in one electrochemical energy device face grand challenge due to incompatibility between H+ and OH-. Herein, we report an alkali-acid Zn-MoO3 hybrid battery that employ H+ and OH- as charge carriers of cathode and anode, respectively, in which the insertion/deinsertion of H+ take place on layer structured MoO3 cathode in acid while OH- are involved in alkaline conversion Zn anode, which offers a promising route to well address the incompatible issues of H+ and OH- in one electrolyte. The as-built hybrid battery can deliver a high open-circuit voltage of 1.85 V, a high rate capability, a high capacity of 158 mAh g-1 at a current density of 5 A g-1, and excellent capacity retention of above 90% over 200 cycles. This work sheds light on the development of aqueous energy devices with high voltage and energy density through materials engineering and device optimization.

Introduction

Electrochemical energy storage and conversion systems play a crucial role in the development of renewable energy for a sustainable future.1,2,3 Among these systems, aqueous-based batteries that employing metal ions as charge carriers, such as Zn-ion battery,4,5,6 have drawn worldwide attentions due to the advantages of environmental benignity, high safety, high efficiency, and fast kinetics. Whilst nonmetal ions battery,7,8,9,10 such as hydrogen ions (H+), hydroxide ions (OH-), NO3-, and NH4+, receive rare research interest it deserved because they are actually ideal charge carriers for rechargeable batteries, thanks to their small size, high ion mobility, low cost, and wide flexibility compared to the metal ions.11,12 Moreover, it remains a grand challenge for the development of rechargeable battery with dual-nonmetal ions as charge carriers of both anode and cathode.13,14,15 In this regard, it is of great significance to explore the feasibility of developing aqueous batteries with dual-nonmetal ions as charge carriers and to clarify the associated electrochemical mechanism. Of various nonmetal ions, H+ and OH- are the ideal candidates as charge carriers for the dual-nonmetal ions battery with hydrogen insertion/deinsertion in cathode and OH- involved in conversion anode (e.g., Zn, Al, Mg anode), respectively. To this end, at least two critical issues should be addressed. On one hand, an essential prerequisite for implementing such hybrid electrochemical device is to explore suitable cathode materials with capability for reversible H+ insertion/deinsertion. On the other hand, it is a daunting challenge to integrate H+ and OH- in one electrochemical system because these two ions would react quickly once mixed.

Orthorhombic α-MoO3 is one of the promising materials for H+ storage,16,17 which is appropriate for the insertion/deinsertion of H+ due to its layered structure.18,19,20 However, the poor conductivity and the limited electrochemical activity of α-MoO3 greatly restrict its electrochemical H+ storage capability and
thus behave low specific capacity and fast decay.\textsuperscript{21, 22} Accordingly, efforts have been made to improve the conductivity of $\alpha$-MoO\textsubscript{3}, typically by coating of conductive polymers on the surface of MoO\textsubscript{3},\textsuperscript{23, 24, 25} such as polyaniline (PANI), polypyrrole (Ppy), owing to their merits of good stability, low cost, and good conductivity, which is beneficial to facilitate electrons transfer and to expedite ions exchange, in this manner can the associated performance be improved to a certain extent, there is great space for further improvement yet.\textsuperscript{26, 27}

The bottleneck for such electrochemical device with non-mental ions storage is the thermal stability windows of 1.23 V, which greatly limits the energy density that is directly related to the working voltage according to the equation ($E = C_{sp} \times V$).\textsuperscript{28, 29} Hybrid electrochemical devices by coupling acidic cathode with alkaline anode were reportedly to be capable of broadening the voltage window of aqueous battery,\textsuperscript{30, 31, 32, 33, 34, 35} which inspire us to accomplish the idea to develop dual-nonmetal ions H\textsuperscript{+}/OH\textsuperscript{-} battery. We herein report a surface engineering and defect manufacturing route for fabrication of vacancy-riced MoO\textsubscript{3} porous nanobelt (v-MoO\textsubscript{3} PNB), which hold abundant oxygen defects and enlarged surface area, leading to more exposed active sites and improved electrical conductivity and allowing faster kinetics for H\textsuperscript{+} insertion/deinsertion. We demonstrate the v-MoO\textsubscript{3} PNB exhibits a specific capacity of 210 mAh g\textsuperscript{-1} at 5 A g\textsuperscript{-1} and a high rate performance. Furthermore, we put forward an alkali-acid Zn-MoO\textsubscript{3} hybrid battery by coupling alkaline Zn anode with acidic v-MoO\textsubscript{3} PNB cathode that can liberate impressively high voltage and energy density.

**Results**

The synthesis process of v-MoO\textsubscript{3} PNB is schematically illustrated (Fig. S1, supporting information), which start a modified hydrothermal method reported previously for the synthesis of MoO\textsubscript{3} nanobelt (MoO\textsubscript{3} NB),\textsuperscript{18} which was then treated by FeCl\textsubscript{3} solution.\textsuperscript{36} The v-MoO\textsubscript{3} PNB was finally obtained by partially reduction upon thermally annealing with NaH\textsubscript{2}PO\textsubscript{2}·H\textsubscript{2}O as reductant at 250 °C for 1 h according to the following reactions:

\[
2 \text{NaH}_2\text{PO}_2\cdot\text{H}_2\text{O} (s) \rightarrow \text{PH}_3 (g) + \text{Na}_2\text{HPO}_4 (s) + 2 \text{HO}_2 (g)
\]

\[
\text{MoO}_3 + \text{PH}_3 \rightarrow \text{MoO}_{3-x} + x/4 \text{H}_3\text{PO}_4
\]

The as-prepared v-MoO\textsubscript{3} PNB, similar to that of MoO\textsubscript{3} NB, shows typical x-ray diffraction (XRD) patterns of orthorhombic MoO\textsubscript{3} phase (JCPDS#35-0609) with three dominant peaks that can be well indexed to (020), (040), and (060) crystalline facets. (Fig. 1a). Notably, one can obviously observe negative shifts of peak (020), (040), and (060) for v-MoO\textsubscript{3} PNB relative to those of MoO\textsubscript{3} NB (Fig. S2, supporting information), implying the increase of lattice spacing in v-MoO\textsubscript{3} PNB arising from the introduction of oxygen vacancies.\textsuperscript{37, 38} Fig. 1b-c show the typical scanning electron microscopy (SEM) images of MoO\textsubscript{3} NB, displaying a smooth nanobelt morphology with an average width of 240 nm and lengths about 5-10
μm (Fig. S3, supporting information), while the v-MoO$_3$ PNB show an eminently rough surface due to the etching treatment of FeCl$_3$ solution (Fig. 1d-e) with well maintaining nanobelt structure (Fig. S4, supporting information). It is noted that the color changes from the grey-white of MoO$_3$ NB to the blue of the v-MoO$_3$ PNB (Fig. S5, supporting information), further confirming inducing the surface defects of oxygen vacancies. The transmission electron microscopy (TEM) image convinces the existence of the porous structure in v-MoO$_3$ PNB (Fig. 1f). High-resolution TEM image (Fig. 1g) implies that the well-defined lattice fringe with an interplanar distance of 3.44 Å, corresponding the (020) plane of MoO$_3$. Moreover, some atomic-leveled distortion could be clearly observed (remarked by red dots, also see Fig. S6, supporting information), which is due to the presence of oxygen vacancies. The selected area electron diffraction (SAED) pattern was shown in Fig.1h, indicating the single-crystalline nature of the v-MoO$_3$ PNB, which is attributed to the (010) zone axis diffraction.

Raman spectroscopy and electron paramagnetic resonance (EPR) spectroscopy were carried out to study the samples. Both the MoO$_3$ NB and the v-MoO$_3$ PNB show three sharp Raman bands located at 663 (B2g/B3g, vas, O-Mo-O stretch), 816 (Ag, vas, Mo=O stretch) and 993 cm$^{-1}$ (Ag, vas, Mo=O stretch, Fig. 2a),$^{38}$ confirming they are orthorhombic structure of α-MoO$_3$. The v-MoO$_3$ PNB exhibits a remarkable reduction in Raman peak intensity compared to the MoO$_3$ NB, implying the successful introduction of oxygen vacancies. Fig. 2b shows the Electron Paramagnetic Resonance (EPR) spectroscopy of MoO$_3$ NB and v-MoO$_3$ PNB. The MoO$_3$ NB almost shows no EPR signal while the v-MoO$_3$ PNB manifests a remarkable EPR signal in fields of 3250-3750 Gs. The g1 can be ascribed to the O$^-$ as the paramagnetic center and the g2 is related to the Mo$^{5+}$ as the paramagnetic center.$^{39,40}$ The presence of Mo$^{5+}$ further indicates the presence of oxygen vacancy in v-MoO$_3$ PNB.

X-ray photoelectron spectroscopy (XPS) was conducted to further investigate the surface properties and chemical composition of the samples. The survey spectroscopy shows the sign of Mo, C, and O elements in both MoO$_3$ NB and v-MoO$_3$ PNB (Fig. S7, supporting information). Fig. 2c presents the high-resolution XPS spectra of Mo 3d, which can be divided into four peaks, 236.1 eV for Mo$^{6+}$ 3d$_{3/2}$, 232.9 eV for Mo$^{6+}$ 3d$_{5/2}$, 235.4 eV for Mo$^{5+}$ 3d$_{3/2}$, and 232.2 eV for Mo$^{5+}$ 3d$_{5/2}$, respectively.$^{41,42}$ The atomic ratio of Mo$^{5+}$/Mo$^{6+}$ can be employed to character the oxygen vacancies of MoO$_3$. For MoO$_3$ NB, the atomic ratio of Mo$^{5+}$/Mo$^{6+}$ is estimated to be 0.13 (corresponding to MoO$_2.93$), while the corresponding value for v-MoO$_3$ PNB increases to 0.38 (corresponding to MoO$_2.82$), suggesting that the partial reduction of MoO$_3$ and the oxygen vacancies have been increased after the reduction treatment. The peak of 530.6 eV is observed for both MoO$_3$ and v-MoO$_3$ PNB from the O1s core-level XPS spectra (Fig. 2d), which is ascribed to the Mo-O bond. Moreover, the O 1s XPS peak of 531.4 eV for MoO$_3$ NB indicates the absorption of OH$^-$ on the surface of MoO$_3$ NB, while for the v-MoO$_3$ PNB, the peak corresponding to OH$^-$ is missing, and there appear two peaks located at 532.4 and 531.2 eV that can be assigned to the sign of PO$_3^-$ and H$_2$PO$_4^-$,$^{43}$ further confirming the partial reduction of MoO$_3$ by phosphate ions during the annealing process.
To evaluate the $\text{H}^+$ storage capability, cyclic voltammetry (CV) tests were carried out in 1.0 M $\text{H}_2\text{SO}_4$ with a standard three-electrode system with Ag/AgCl as reference electrode, Pt wire as counter electrode, and the MoO$_3$ modified carbon paper (1*1 cm$^2$) as working electrode, respectively. Fig. 3a shows the first three CV curves of v-MoO$_3$ PNB at a scan rate of 1 mV s$^{-1}$ at the potential range from -0.5 to 0.3 V. One can observe three pairs of redox peaks of 0.074 V/0.01 V, 0.032 V/-0.04 V, and -0.371 V/-0.384 V that are related to the insertion and deinsertion of $\text{H}^+$ into the v-MoO$_3$ PNB electrode. Notably, the peak current of v-MoO$_3$ PNB is larger than that of MoO$_3$ NB (Fig. 3b), implying a higher $\text{H}^+$ storage capacity for v-MoO$_3$ PNB, which can be rationally attributed to the higher conductivity (Fig. S8, supporting information) and more activity sites derived from large specific surface area (Fig. S9, supporting information). Moreover, the reaction kinetics of $\text{H}^+$ insertion and deinsertion were further studied by recording the CV curves at different scan rates from 0.5 to 10 mV s$^{-1}$ (Fig. 3c). The peak currents and the peak separations increase along with the scan rate increases, which is due to the enhanced polarization at high scan rates. The Randles-Sevcik equation was employed to determine the relationship between the peak currents ($i_p$) and scan rate ($v$). The $i_p$ linearly increases with the square root of the scan rate ($v^{1/2}$) over the scan rate range, with the excellent linearity close to 1 (Fig. 3d), indicating a diffusion process control of the $\text{H}^+$ insertion and deinsertion on the v-MoO$_3$ PNB electrode.

The charge and discharge profiles from 1 A g$^{-1}$ to 20 A g$^{-1}$ of the v-MoO$_3$ PNB are shown in Fig. 4a. Even at an ultra-high current of 20 A g$^{-1}$, three obvious pairs of charge and discharge plateaus can be observed, which match well with the three-step redox behavior in the CV curves. While the charge and discharge plateaus of MoO$_3$ NB can't be recognized at large current (Fig. S10, supporting information), implying the high rate capability for the v-MoO$_3$ PNB thanks to its improved conductivity. Fig. 4b shows the capacity at different current density of the v-MoO$_3$ PNB, which delivers discharge capacities of approximately 248.2, 245.4, 210.8, and 198.7 mAh g$^{-1}$ at currents of 1, 5, 10, and 20 A g$^{-1}$, respectively. The Coulombic efficiency is in the range of 97 - 99% can be obtained when the current is reduced to 1 A g$^{-1}$. However, the MoO$_3$ NB exhibits a poor rate performance with low specific capacity and inferior capacity recovery (Fig. S11, supporting information). Fig. 4c shows the stability of the v-MoO$_3$ PNB for $\text{H}^+$ insertion and deinsertion. At a current of 10 A g$^{-1}$, above 92% of its initial capacity can remain with an average Columbia efficiency of 96% after 200 cycles, which is superior to those of MoO$_3$ NB (Fig. S12, supporting information).

Given its quite good $\text{H}^+$ storage capability, we developed a alkali-acid Zn-MoO$_3$ hybrid battery that $\text{OH}^-$ are involved on alkaline Zn conversion anode while $\text{H}^+$ insertion/deinsertion takes place in acidic v-MoO$_3$ PNB cathode (Fig. 5a).

Anode: Zn + 2$\text{OH}^-$ $\leftrightarrow$ ZnO + $\text{H}_2\text{O}$

Cathode: MoO$_{3-x}$ + $\text{H}^+$ $\leftrightarrow$ $\text{H}_y\text{MoO}_{3-x}$
In this as-developed hybrid device, the redox reactions of anode and cathode can proceed in their optimal conditions with potential of harvesting the so-called electrochemical neutralization energy (ENE),\textsuperscript{44, 45, 46, 47, 48} which can significantly enhance the voltage and energy density of energy devices. Fig. 5b shows the CV curves of the Zn anode in alkali and the v-MoO\textsubscript{3} PNB cathode acid at a scan rate of 1 mV s\textsuperscript{-1}. Both electrodes show redox activity at their individual potential windows, which indicates the availability and feasibility for fabricating alkali-acid Zn-MoO\textsubscript{3} hybrid battery. The as-constructed alkali-acid Zn-MoO\textsubscript{3} hybrid battery (Fig. 5b) shows one prominent pair of redox peaks in the potential range of 1.2 V to 1.6 V. As a result, the battery shows a high open-circuit voltage (OCV) of about 1.85 V (Fig. 5c), higher than most of aqueous battery.\textsuperscript{49, 50, 51, 52, 53} And the value is constant for 60 mins, implying the decent stability of the hybrid battery. Moreover, a single battery can power a red light-emitting diode (LED, 1.8-2.2 V, Fig. S13, supporting information), further demonstrating the high voltage of the as-built battery. It is noted that the OCV of the battery varies when the electrolyte is different (Fig. S14, supporting information) because the H\textsuperscript{+} insertion and deinsertion are sensitive to the pH value of electrolytes, including the current and potential (Fig. S15, supporting information).

Fig. 5d shows the charge and discharge profiles from 1 A g\textsuperscript{-1} to 10 A g\textsuperscript{-1} of the alkali-acid Zn-MoO\textsubscript{3} hybrid battery. The distinct charge and discharge plateaus can be observed in all curves at various current density. The alkali-acid Zn-MoO\textsubscript{3} hybrid battery can deliver a discharge capacities of 198.2, 170.2, 157.8, and 139.2 mAh g\textsuperscript{-1} at currents of 1, 2, 5, and 10 A g\textsuperscript{-1}, respectively (Fig. 5e), which implies the battery can afford an excellent rate performance. Moreover, when the current density was back to 1 A g\textsuperscript{-1}, the reversible specific capacity could be recovered, indicating excellent reversibility of the battery even after high rate current. Meanwhile, high Coulombic efficiency in the range of 94 - 98\% can be achieved. Fig. 5f exhibits the charge and discharge profiles (GCD) of the alkali-acid Zn-MoO\textsubscript{3} hybrid battery in different cycle number at a current density of 5 A g\textsuperscript{-1}, in which one can clearly observe two pairs of GCD voltage plateaus. The dominant GCD voltage plateaus are located at about 1.45 V and 1.85 V for the first charge-discharge process, and they are positioned at a stable level of about 1.91 V and 1.51 V in the following cycles, indicating that the alkali-acid Zn-MoO\textsubscript{3} hybrid battery shows a good reversibility and cycling stability. Furthermore, long-term cycling performance of the alkali-acid Zn-MoO\textsubscript{3} hybrid battery confirms the excellent stability. As shown in Fig. 5g, above 90\% of its initial capacity can be achieved with an average Columbia efficiency of 95\% after 200 cycles at a current of 5 A g\textsuperscript{-1}. The phase of the v-MoO\textsubscript{3} PNB has not been changed after long-term stability test, except for peaks from Naon at 18º and 26.4º, and crystalline carbon paper at about 25º (Fig. S16, Supporting Information). In addition, the morphology and microstructure of the v-MoO\textsubscript{3} PNB also keep almost unchanged, as demonstrated by the SEM images of the material (Fig. S17, Supporting Information). Moreover, the CV curve of Zn anode shifts for high potential, while that of v-MoO\textsubscript{3} PNB cathode shifts to low potential (Fig. S18, Supporting Information), which may be due to the crossover of H\textsuperscript{+} and OH\textsuperscript{-}. For this purpose, we monitor the pH value variation of the catholyte and anolyte during cycling. The concentration of H\textsuperscript{+} and OH\textsuperscript{-} decrease along with cycling.
(Fig. S19, Supporting Information), which induces the capacity decay of the alkali-acid Zn-MoO$_3$ hybrid battery.

To investigate the mechanism of the alkali-acid Zn-MoO$_3$ hybrid battery, the ex-situ XRD measurements of v-MoO$_3$ PNB electrode were performed during the charge and discharge process (Fig. 6). As shown in Fig. 6b, all the XRD patterns during the charge-discharge processes show three predominant peaks of (020), (040) and (060), indicating that no phase transition exists in the processes, which suggests a solid solution reaction during H$^+$ ions insertion and deinsertion. Moreover, the peak located at about 18º is assigned to the Naon. When discharged to 1.0 V, the peak at 12.7º for the (020) planes of the v-MoO$_3$ PNB shifts to 12.6 V, associated with the (002) planes of H$_{0.88}$MoO$_3$, implying the H$^+$ ions have been inserted into the v-MoO$_3$ PNB. When charged to 1.7 V and 2.2 V, the peak derived from the (020) planes returns to 12.67º and 12.7º. During the subsequent discharge process, the (020) peak shifts from 12.7º to 12.63º. These observations reveal that the insertion and deinsertion of H$^+$ are reversible on the v-MoO$_3$ PNB.

**Discussion**

In summary, we have demonstrated a novel alkali-acid Zn-MoO$_3$ hybrid battery that hydroxide ions (OH$^-$) can be consumed/released on the Zn anode in alkali and hydrogen ions (H$^+$) can be inserted/deinserted into/from MoO$_3$ on the cathode in acid. The hybrid battery exhibits a high voltage of 1.85 V and a reversible capacity of 157 mAh g$^{-1}$ with a near 100% Coulombic efficiency at a high current density of 5 A g$^{-1}$, which is contributed to the fast kinetics of charge carriers of H$^+$ and OH$^-$, improved conductivity and active sites induced by high density of oxygen vacancies in v-MoO$_3$ PNB, and the utilization of electrochemical neutralization energy. The present work may open a new avenue for developing high voltage and high energy density aqueous electrochemical energy devices.

**Methods**

**Preparation of $\alpha$-MoO$_3$ nanobelt (MoO$_3$ NB):** Typically, 10 mL of saturated ammonium heptamolybdate tetrahydrate was added in a beaker. 20 mL of 10% HNO$_3$ solution was dropped into the beaker with the assistance of stirring. The pH of the mixed solution was adjusted to about 1 by 20% HNO$_3$. Then, the obtained solutions were transferred into a 50 mL Teflon-line autoclave and heated at 180 ºC for 40 h. The $\alpha$-MoO$_3$ nanobelt was obtained by washing with absolute ethanol and distilled water for several times and then drying at 60 ºC.

**Preparation of vacancies abundant MoO$_3$ porous nanobelt (v-MoO$_3$ PNB):** 100 mg of as-prepared MoO$_3$ was dispersed in 20 mL of 0.1 M FeCl$_3$ solution, and then stirring for 6 h. The product of MoO$_3$ nanobelt with a porous structure (MoO$_3$ PNB) was collected after washing and drying. 50 mg of the as-collected product was placed in a combustion boat, and 5 g NaH$_2$PO$_4$·H$_2$O at the upstream side of the tube
furnace. The v-MoO$_3$ PNB was obtained by calcining the MoO$_3$ PNB powder at 250 ºC for 1 h in the Ar atmosphere.

**Characterization**

The morphologies of samples were checked by field-emission scanning electron microscope (FESEM; Hitachi, SU8010, 5 kV) and transmission electron microscope (TEM, FEI, F20, 200 kV). The phase of products was performed on the powder X-ray diffraction (Hitachi, Miniflex600). X-ray photoelectron spectra (XPS) were collected by ESCALAB 250Xi (Thermo Scientific) XPS spectrometer with an Al Kα as the excitation source (1486.6 eV). The N$_2$ adsorption-desorption isotherms were accomplished on a Micrometerics Instrument Corporation sorption analyzer at 77 K (Micrometerics TriStar II 3020), from which we can obtain the information of specific are and pore properties for samples.

**Hydrogen ions insertion/deinsertion measurements**

The electrochemical measurements were carried out on a CHI 760E electrochemical work station employing a typical three-electrode system in the solution of 1 M H$_2$SO$_4$, in which MoO$_3$ modified carbon paper electrode, Ag/AgCl, and Pt mesh were used as working electrode, the counter electrode, and the reference electrode, respectively. 10 mg of MoO$_3$ material was dispersed and sonicated in 500 µL of a solution containing 250 µL of denied-ion water, 50 µL of Nafion (5%, Dupont) and 200 µL of ethanol, forming the link. The MoO$_3$ modified carbon paper electrode was prepared by dropping 100 µL of ink on the carbon paper (efficient are, 1 cm$^2$) with the mass loading of 2 mg cm$^{-2}$.

**Assembly and tests of alkali-acid Zn-MoO$_3$ hybrid battery**

To assemble alkali-acid Zn-MoO$_3$ hybrid battery, MoO$_3$ modified carbon paper electrode was inserted in 2 M H$_2$SO$_4$ solution and the Zn plate was immersed in 4 M NaOH. Between which a Nafion 117 membrane was employed to separate the acid-alkali solution, avoiding bulk neutralization. The Nafion membrane was treated by 1 M H$_2$SO$_4$, then 3% H$_2$O$_2$ at the temperature of 80 ºC for 1 h, respectively. Finally, the Nafion membrane was converted to the Na$^+$ conductive membrane after the treatment of NaOH at the temperature of 80 ºC for 1 h. The membrane was stored in the 1 M NaSO$_4$ solution. The open-circuit voltage, CV curves, and open-circuit voltage profiles were recorded on the CHI 760E electrochemical working station. GCD tests were conducted on a battery test system (CT2001 A, LAND).

**Figures**
Figure 1

(a) XRD patterns of MoO3 NB and v-MoO3 PNB. (b, c) SEM images of MoO3 NB. (d, e) SEM images; (f) TEM image (g) HRTEM image; and (h) SAED of v-MoO3 PNB.
Figure 2

(a) Raman spectra; (b) EPR spectroscopy of MoO$_3$ NB and v-MoO$_3$ PNB. (c) Mo 3d core level; (d) O 1s core level of XPS for MoO$_3$ NB and v-MoO$_3$ PNB.
Figure 3

(a) CV curves of the v-MoO3 PNB electrode for the first three cycles at a scan rate of 1 mV s⁻¹. (b) CV curves of v-MoO3 PNB and MoO3 NB electrodes at a scan rate of 10 mV s⁻¹. (c) CV curves of v-MoO3 PNB at different scan rates from 0.5 to 10 mV s⁻¹. (d) The corresponding plots of peak currents vs. square root of scan rates of v-MoO3 PNB.
Figure 4

(a) Charge-discharge profiles at different current; (b) Rate performance at current densities from 1 to 20 A g⁻¹; Cycle performance and Coulombic efficiency at a current density of 10 A g⁻¹ of v-MoO₃ PNB electrode.
Figure 5

Electrochemical performance of the as-built alkali-acid Zn-MoO3 hybrid battery. (a) Schematic diagram of the as-built Zn-MoO3 hybrid battery; (b) CV curves of Zn anode, v-MoO3 PNB cathode, and the as-built Zn-MoO3 hybrid battery with a scan rate of 1 mV s⁻¹. (c) Open-circuit voltage (OCV); (d) Charge-discharge profiles at different current; (e) Rate performance at current densities from 1 to 10 A g⁻¹; (f) Charge-discharge profiles at a current density of 5 A g⁻¹ at different cycle number; (g) Long-term cycling performance and corresponding Coulombic efficiency at a current density of 5 A g⁻¹ of the as-proposed Zn-MoO3 hybrid battery.
Figure 6

(a) Charge and discharge profiles of the v-MoO3 PNB electrode in the Zn-MoO3 hybrid battery. (b) Ex-situ XRD patterns of the v-MoO3 PNB at different charge-discharge status. (c) Magnified XRD pattern at the range of 10-15°.
