The non-ducted propagation characteristics of the VLF waves in the inner magnetosphere were studied with respect to their frequency, source localization, and initial angle $\theta_0$ between the wave-normal and the background magnetic field. The ray tracing software based on multi-components cold plasma approach was developed by use of the IGRF magnetic field model and the GCPM model of plasma density. We described dynamics of the wave-normals direction during its propagation and magnetospheric reflection. We showed that whistler waves can be reflected when lower hybrid resonance frequency becomes greater than the wave frequency: $\omega_{LH} > \omega$. It corresponds to magnetic latitude $\lambda \sim 50^\circ$. The simulation results confirmed the inapplicability of the quasi-longitudinal approximation to describe the propagation of magnetospheric whistlers. The simulation results of chorus emissions propagation, which used realistic distributions of waves on the initial parameters was presented. Particularly, we obtained distributions of chorus emission waves in dependence on the wave-normal directions for different magnetic latitudes. It is required for studying diffusive processes in the radiation belts. The results were found to be in a good agreement with the CLUSTER STAFF-SA measurements.

INTRODUCTION

The most intense electromagnetic plasma waves observed in Earth’s radiation belts and outer magnetosphere, discrete ELF/VLF chorus emissions, are characterized by rising and falling tones in the few hundred to several thousand Hertz frequency range (Burton and Holzer, 1974; Tsurutani and Smith, 1974). See also reviews by (Omura et al., 1991) and (Sazhin and Hayakawa, 1992) and references therein. Critical to radiation belt dynamics, these emissions have been studied intensively because they play a crucial role in the acceleration of energetic electrons in the outer radiation belt. Typically ELF/VLF chorus emissions are observed near the magnetic equatorial plane in the dawn and dayside outer magnetosphere (Omura et al., 1991). They have attracted special attention recently because they were observed as waveforms, allowing determination of their wave normal vector distributions. (Burton and Holzer, 1974) were the first who determined chorus normal vector distributions using the search coil magnetometer aboard OGO5, near the equator, at geosynchronous altitude. Chorus wave normal directions at $\leq 17^\circ$ magnetic latitudes and $L$-shells $\sim 7.6$ were later studied by (Hayakawa et al., 1984). Analysis of wave normals and Poynting fluxes for separate emission elements has shown that the emissions are generated in proximity to the geomagnetic equator and propagate to higher latitudes in a non-ducted whistler mode (Burton and Holzer, 1974; Hayakawa et al., 1984) or duct mode (Yearby et al., 2011). Chorus emissions are usually observed in the Earth’s dawn sector between 23:00 and 13:00 MLT (Tsurutani and Smith, 1974). These emissions, which propagate in the whistler mode, consist of two broad frequency bands on either side of half local equatorial gyrofrequency $\omega_{ce}$ at the geomagnetic equator along the magnetic field line on which the waves are observed (Tsurutani and Smith, 1974, 1977). If present, the upper band exists in the $\omega/\omega_{ce} \approx 0.5–0.75$ frequency range and contains discrete chorus elements rising at a few kHz/s. The lower band exists in the $\omega/\omega_{ce} \approx 0.1–0.5$ frequency range and contains both elements rising at a few kHz/s and diffuse elements. In the inner magnetosphere, $L$-shell is $\sim 2–6$, wave generation onset has been shown to be associated with substorm electron injections (Goldstein and Tsurutani, 1984). Chorus in the radiation belts is believed to be generated through electron cyclotron instability when the distribution of energetic electrons in the 5 to 150 keV range is strongly anisotropic (Trakhtengerts, 1999). This has been shown to be the case in recent studies of such waves during electron injections. Chorus waves in the outer dayside region have received further attention recently, especially as the THEMIS mission was...
able to extend previous observations beyond \( L \sim 7 \) to \( L \sim 13 \). Dayside quiet-time chorus cannot be explained in the absence of injections, however, and remains an area of active study. Other chorus generation occurs in the local minimum magnetic field regions near the dayside magnetopause on the magnetic latitude near \( \pm (40^\circ - 50^\circ) \) (Tsurutani and Smith, 1977). The spatial and temporal dependencies of high-latitude chorus parameters are considerably different from those of the chorus generated near the magnetic equator. The frequency range of the high-latitude chorus is similar to chorus waves generated near the magnetic equator at \( L > 10 \) but their spectral power distribution exhibits two maxima: \((0.15-0.15)\omega_{ce}\) and \((0.25-0.30)\omega_{ce}\). These emissions are mainly detected within \(1-2 R_E\) from the magnetopause (Tsurutani and Smith, 1977).

Before the Cluster mission, observations of ELF/VLF chorus emissions were mainly made by single spacecraft, such as ISEE 1 and ISEE 2, which observed many similar events (Gurnett et al., 1979). Recent Poynting flux and polarization measurements aboard Cluster spacecraft confirmed that the chorus source is located close to the equatorial plane (Agapitov et al., 2011b, 2012; Parrot et al., 2003; SantolÃčÃnk et al., 2005). Measurements around the magnetic equator demonstrate the change in sign of the parallel component of the Poynting vector when the satellites cross the equator region. Poynting vector flux analysis indicates that the central position of the chorus source fluctuates along the background magnetic field within \(1000-2000\) km of the geomagnetic equatorial plane in the timescale of minutes. In studies of chorus emission generation mechanisms, (Helliwell, 1967) and (Trakhtengerts, 1999) gave theoretical estimates of the scale size of the wave generation region. Attempts to estimate the scale size experimentally were made using coordinated CLUSTER (Agapitov et al., 2010; SantolÃčÃnk et al., 2003) and more recently THEMIS (Agapitov et al., 2011a,c), observations in the radiation belt region.

Although the magnetospheric reflection of whistler chorus is discussed and simulated in a number of papers, such as (Helliwell, 1967) and (Burton and Holzer, 1974), experimental confirmation is scarce. Continuous increase in the angle between the wave vector and background magnetic field for several cases of reflected chorus in the outer magnetosphere, based on Ogo 5 measurements, was shown in (Burton and Holzer, 1974). In (Parrot et al., 2003) the Poynting vector and wave normal directions of chorus waves were analyzed using Cluster STAFF-SA measurements of spectral matrices with a 4 s time resolution (Agapitov et al., 2011b). Another Cluster spacecraft observed waves propagating from the geomagnetic equator region and reflected waves that reached a lower hybrid resonance reflection at low altitudes and returned to the equator at another location with a lower intensity (Agapitov et al., 2010). (Parrot et al., 2003) corroborated this interpretation using ray tracing analysis. (Bortnik et al., 2008) demonstrated wave reflection, refraction and resultant inward radial propagation across \( L \)-shells and MLT over several \( R_E \). The agreement between models and THEMIS data in the above study (Bortnik et al., 2008) encourages use of the ray tracing technique to determine evolution and consequences of chorus waves outside the plasmasphere. To this end it is necessary to develop a numerical ray tracing code that can reproduce wave distributions based on direct measurements and then to fill up the observed distributions by the distributions obtained from simulations.

In this paper we obtain the distribution of chorus wave parameters, taking as a basis Cluster observations and to study influence of the equatorial azimuthal wave normal distribution to wave properties at high latitudes.

**MODEL DESCRIPTION**

In this section, we present the numerical model which computes ray trajectories of chorus emissions (ELF/VLF whistler modes) in the inner magnetosphere using the approximation of the cold collision-less multi-components plasma. The calculation is carried out making use of realistic plasma density parameters and pre-selected initial wave distributions.

The electromagnetic field should be presented in the following form \( E, B(\vec{k}, \omega, \vec{r}, t) = e^{-i(\omega t - k \vec{r})} \), where field amplitude varies slowly compared with the eikonal \( \varphi \) (written as a four-dimensional line integral). In such an approximation \( \vec{k} = \nabla \varphi(\vec{r}) \) and the equations are transformed into a system of eikonal equations. The Maxwell’s equations give the equation system for \( \vec{E} \) components:

\[
\mathcal{M} \vec{E} = \vec{k}(k \vec{E}) - \frac{\omega^2}{c^2} \hat{e} \tag{1}
\]

Then, the condition of solvability gives the dispersion relation:

\[
M = \left\| \mathcal{M}(\vec{k}, \omega, \vec{r}, t) \right\| = 0
\]
By use of the approximation of cold collisionless plasma in the background magnetic field in the field aligned coordinate system where $\vec{B}_0$ is along $Z$ with the angle $\theta$ between wave normal and the background magnetic field $\vec{B}_0$, the dispersion relation has the form (Stix, 1962):

$$
\left(1 - \frac{\omega^2}{\omega_{pe}^2 + \omega_{pi}^2}\right) \left[\frac{\omega}{\omega_{ce}} \left(1 + \frac{\omega_{pe}^2 + \omega_{pi}^2}{c^2 k^2 - \omega^2}\right) - \frac{\omega_{ci}}{\omega} \right] - (1 - \gamma)^2 + \left[1 + \gamma \left(\frac{\omega_{pe}^2 + \omega_{pi}^2}{c^2 k^2 - \omega^2}\right)ight] - 1 + \gamma - \left(\frac{\omega_{ci}}{\omega}\right)^2 \frac{ck \sin \theta}{c^2 k^2 - \omega^2} = M = 0, \quad (2)
$$

where $\omega_{ce} = \frac{eB_0}{m_e}$ is the local electron gyrofrequency, $\omega_{pe} = \frac{4\pi n e^2}{m_e}$, $\gamma = m_e/m_i = 1/1836.15$. The solutions of the dispersion relation are shown in Fig. 1 for two cases $\omega_{pe} > \omega_{ce}$ and $\omega_{pe} < \omega_{ce}$ respectively. This dispersion relation is used to solve numerically the equation system for the ray tracing:

$$
\frac{d\vec{r}}{dt} = \frac{\partial \omega}{\partial \vec{k}}, \quad \frac{d\vec{k}}{dt} = -\frac{\partial \omega}{\partial \vec{r}}, \quad (3)
$$

in the following form:

$$
\frac{d\vec{r}}{dt} = -\left(\frac{\partial M}{\partial k}\right) \left(\frac{\partial M}{\partial \omega}\right)^{-1}; \quad \frac{d\vec{k}}{dt} = \left(\frac{\partial M}{\partial \vec{r}}\right) \left(\frac{\partial M}{\partial \omega}\right)^{-1}. \quad (4)
$$

The absolute value of the $\vec{k}$-vector can be obtained from the dispersion relation for whistler waves in a form:

$$
\left(\frac{kc}{\omega}\right)^2 = \left(RL \sin^2 \theta + PS(1 + \cos^2 \theta) - \left[(RL \sin^2 \theta + PS(1 + \cos^2 \theta))^2 - 4PRL \left(S \sin^2 \theta + P \cos^2 \theta\right)\right]^{1/2}\right) \times \left(2 \left[S \sin^2 \theta + P \cos^2 \theta\right]\right)^{-1}, \quad (5)
$$

where $R$, $L$, $P$, and $S$ are the polarization parameters, following the notation by (Stix, 1962):

$$
R = 1 - \left(\frac{\omega_{pe}}{\omega_{ce}}\right)^2 \left(\frac{\omega_{ce}}{\omega}\right) \left[\left(\frac{\omega_{ce}}{\omega}\right) - 1\right]^{-1},
$$

$$
L = 1 - \left(\frac{\omega_{pe}}{\omega_{ce}}\right)^2 \left(\frac{\omega_{ce}}{\omega}\right) \left[\left(\frac{\omega_{ce}}{\omega}\right) + 1\right]^{-1},
$$

$$
S = \frac{R + L}{2}, \quad D = \frac{R - L}{2}, \quad P = 1 - \left(\frac{\omega_{pe}}{\omega}\right)^2,
$$

where $\omega_{pe}$ is the local plasma frequency.
Fig. 1: Dispersion of electromagnetic waves for two cases $\omega_{pe} > \omega_{ce}$ (a) and $\omega_{pe} < \omega_{ce}$ (b).
Magnetospheric chorus emissions are commonly observed between 2.5 $R_E$ and 10 $R_E$. Near 2.5 $R_E$ the Earth’s core magnetic field is assumed to have a tilted dipolar structure with the dipole magnetic momentum corresponding to year 2005 epoch, and an analytical model includes the contribution of sources external to the Earth (namely magnetopause, tail and ring currents) at larger altitudes (Olson and Pittox, 1974). It is valid for all tilts of the Earth’s dipole axis during rather quiet magnetosphere ($K_p < 4$), and has been optimized for the near-Earth region (from 2 $R_E$ to 15 $R_E$). To obtain densities of the magnetospheric plasma species throughout the entire volume of the inner magnetosphere we use the Global Core Plasma Model (Gallagher et al., 2000) (more detailed description of the used models see in (Breuillard et al., 2012)).

**CHORUS WAVE NORMAL PROPERTIES IN THE OUTER RADIATION BELT**

The behavior of the numerical distribution of poleward rays is thus very consistent with the observed distribution presented in Fig 2e from (Agapitov et al., 2011b), where the similar wave normal angle distribution is constructed using the CLUSTER STAFF-SA measurements from years 2001 to 2009. The good agreement is confirmed (Breuillard et al., 2012). The distributions obtained from experimental data and as a result of numerical simulations both exhibit the same tendency, i.e. a rapid increase of the mean value and variance with the growth of $\lambda$. It was shown that starting with $\vec{k}$ direction close to the direction of the background magnetic field near the equator, wave-directions diverge from field aligned direction very fast and already on $\lambda \approx 25^\circ - 35^\circ$ become close to the resonance cone (Fig 2f). When the wave frequency becomes less than the background lower hybrid frequency ($\omega_{LH} \approx \left( \frac{1}{\omega_{pe}} + \frac{1}{\omega_{ci}} \right)^{-1}$), whistler wave transforms to the quasi-electrostatic mode, wave-normal comes to transverse direction, group velocity changes its sign and wave can be reflected (Agapitov et al., 2011b). From the numerical simulation of chorus emissions propagation we obtained distributions of chorus emission waves in dependence on the wave-normal directions for different magnetic latitudes. The deviation of wave-normal direction from the direction of the background magnetic field tends to significant increase of the efficiency of wave-particle interaction in the radiation belts (Artemyev et al., 2012a,b). Due to particle scattering on chorus waves the electron life-time decreases (Mourenas et al., 2012a,b). The wave normal distributions obtained using hot plasma approximations are described in (Breuillard et al., 2012).

The Fig 3 shows the wave power distribution of $\psi^*$ as a function of $\lambda$, where $\psi^* = \theta \cos \varphi$, for chorus waves generated at the equator. Thus, the rays that are initially oriented towards the Earth (i.e. $90^\circ < \varphi_0 < 180^\circ$, in blue lines) have a negative initial $\psi$ at the equator, whereas rays initially directed outward (i.e., $0^\circ < \varphi_0 < 90^\circ$, in red lines) have a positive $\psi^*$, from this figure it can be seen that rays quickly defer outward during their propagation, as none is directed towards the Earth above $\lambda = 40^\circ$. Therefore, the majority of rays generated inward intersect the direction of the local magnetic field for $\lambda < 15^\circ$, which explains the observed strong population of quasi-parallel waves at these low latitudes. For large initial angles, these rays ($-30^\circ < \theta^* < -15^\circ$) can also propagate quasi-parallel to the magnetic field up to latitudes $\sim 30^\circ$, whereas rays initially launched outward quickly tend to resonance cone ($\lambda > 20^\circ$). However, the two ray populations quickly merge and this overlapping forms the major part of the distribution, especially at high latitudes, that propagates obliquely, which is consistent with Cluster observations (Agapitov et al., 2012).

The field aligned population of waves is seen in the spacecraft data at $\lambda \approx 20^\circ - 30^\circ$. The ray tracing does not shows such a group of waves. This can be seen also from the angle $\psi$ between the spacecraft position vector $\vec{r}$ and wave normal shown in Fig 3. $\psi$ is distributed near $90^\circ$ at the equator, and from ray tracing decreases with $\lambda$ to $\sim 60^\circ - 70^\circ$ (Fig 3b). Ray tracing well reproduces $\psi$ distribution from the spacecraft observations shown in Fig 3a. Chorus wave normals tend to rotate outward from the Earth due to magnetic field lines curvature and magnetic field absolute value gradient. The field aligned direction is indicated with black dashed line and the field aligned wave population is observed in $\psi$ distribution at $\lambda \approx 10^\circ - 30^\circ$. These field aligned waves cannot be obtained from the geometric optics approximation used in our paper. The Landau damping is more effective for the oblique waves and wave amplification is more effective for field aligned waves. The wave amplification and wave propagation during the propagation can result in the observed differences between spacecraft observations and numerical simulations and they have to be taken into account, that will be the subject of the future work.
Fig. 2: Ray trace of the whistler wave, generated in the vicinity of the geomagnetic equator with wave-normal directed along the background magnetic field. The wave-normal direction along the trajectory is shown by arrows. The model plasma density (the diffusion equilibrium model) and magnetic field line are shown in grey shades.
Fig. 3: Density probability function of $\theta^* = \theta \cos \varphi$ as a function of latitude $\lambda$ for direct chorus waves generated at the equator. The two different ray populations included in the PDF, i.e. rays for which $90^\circ < \varphi_0 < 180^\circ$ and $0^\circ < \varphi_0 < 90^\circ$, are indicated by blue and red lines, respectively. The distribution intensity of each population is represented by the thickness of the lines.

CONCLUSIONS

In this paper we present a ray tracing technique for the cold magnetized multi-components collision-less plasma that has been developed including realistic plasma density and magnetic field models. Ray tracing was carried out assuming that the wave source is situated at equator. The initial distribution of waves in frequencies and in $\hat{k}$-vectors in the source region was chosen to correspond to statistical distribution dependencies on $\hat{k}$-vectors and frequencies obtained from observations. To this end the weight functions corresponding to distributions inferred from observations were applied to initial set of rays (Breuillard et al., 2012).

Then, making use of our numerical database we show that it is possible to reconstruct chorus wave-
normal distributions as a function of magnetic latitude using weight functions on equator (obtained from experiment). The results of our calculations are in good agreement with statistical distributions found using ten years observational data measured onboard Cluster spacecrafts in [Agapitov et al. (2011b, 2012)].

Chorus wave normal angle distribution at the equator peaks at $\theta \approx 15^\circ - 17^\circ$ and $\theta$ tends to increase fast with latitude reaching the resonance cone at $\lambda \approx 30^\circ - 40^\circ$ and can be reflected at $\lambda \approx 40^\circ - 45^\circ$ where the wave frequency becomes less than the local lower hybrid frequency. Chorus wave normals tend to rotate outward from the direction to the Earth due to the background magnetic field lines curvature and gradients of magnetic field and plasma density. The differences of distributions obtained from the spacecraft observations and from ray tracing can be explained by the Landau damping of the wave during the propagation which is much more effective for oblique wave normal angles. This damping tends to decrease amplitude of oblique chorus waves and results in the concentration of the wave normal distribution near field aligned direction at $\lambda \approx 20^\circ - 35^\circ$. Therefore the existence of oblique wave population in the outer radiation belts tends to more effective electron scattering [Artemyev et al. (2012b)] and decreasing of electron life-time, especially in the L-shell range from 3 to 5.5 [Mourenas et al. (2012c)].
