Abstract. Fixed-parameter algorithms, approximation algorithms and moderately exponential algorithms are three major approaches to algorithms design. While each of them being very active in its own, there is an increasing attention to the connection between different approaches. In particular, whether Independent Set would be better approximable once endowed with subexponential-time or FPT-time is a central question. In this paper, we present a strong link between the linear PCP conjecture and the inapproximability, thus partially answering this question.

1 Introduction

In this paper we look into three approaches to algorithms design: Fixed-parameter algorithms, approximation algorithms and moderately exponential algorithms. These three areas, each of them being very active in its own, have been considered as foreign to each other until recently. Polynomial-time approximation algorithm produces a solution whose quality is guaranteed to lie within a certain range from the optimum. One illustrative problem indicating the development of this area is Independent Set. The approximability of Independent Set within constant ratios\(^1\) has remained as the most important open problems for a long time in the field. It was only after the novel characterization of the NP given by the PCP theorem [1, 2] that impossibility of such approximability has been proven assuming P = NP. Subsequent improvements of the original PCP theorem, leading to corresponding refinements of the characterization of NP have also led to the actual very strong inapproximability result for Independent Set, namely, that it is inapproximable within ratios \(\Omega(n^{\varepsilon-1})\) for any \(\varepsilon > 0\), unless P = NP [31].

Moderately exponential algorithm is to allow exponential running time for the sake of optimality. In this case, the endeavor lies in limiting the growth of

\(^1\) The approximation ratio of an algorithm computing a feasible solution for some problem is the ratio of the value of the solution computed over the optimal value for the problem.
running time function as slow as possible. Parameterized complexity provides an alternative framework to analyze the running time in a more refined way [14, 18]. The aim is to get an $O(f(k) \cdot n^c)$-time algorithm for some constant $c$ (independent of $k$). As these two research programs offer a generous running time compared to polynomial-time approximation algorithms, a growing amount of attention is paid to them as a way to cope with hardness in approximability. The first one deals with moderately exponential approximation. The goal of this program is to explore approximability of highly inapproximable (in polynomial time) problems in superpolynomial or moderately exponential time. Roughly speaking, if a given problem is solvable in time $O^*(\gamma^n)$ but it is NP-hard to approximate within some ratio $r$, we seek $r$-approximation algorithms with complexity - significantly - lower than $O^*(\gamma^n)$. This issue has been considered for several problems such as Set Cover [11, 5], Coloring [3, 4], Independent Set and Vertex Cover [6], Bandwidth [12, 19].

The second research program handles approximation by fixed parameter algorithms. In this approximation framework, we say that a parameterized (with parameter $k$) problem $\Pi$ is $r$-approximable if there exists an algorithm taking as inputs an instance $I$ of $\Pi$ and $k$ and either computes a solution smaller or greater than (depending on whether $\Pi$ is, respectively, a minimization, or a maximization problem) $rk$, or returns “no”, asserting in this case that there is no solution of value at most or at least $k$. This line of research was initiated by three independent works [15, 8, 10]. As an excellent overview in this direction, see [26].

Several natural questions can be asked dealing with these two programs. In particular, the following ones have been asked several times (see for instance [26, 15, 19, 6]) and of great interest:

**Q1** can a highly inapproximable in polynomial time problem be well-approximated in subexponential time?

**Q2** does a highly inapproximable in polynomial time problem become well-approximable in parameterized time?

Few answers have been obtained until now. Regarding **Q1**, negative results can be directly obtained by gap-reductions for certain problems. For instance, Coloring is not approximable within ratio $4/3 - \epsilon$, since this would allow to determine whether a graph is 3-colorable or not in subexponential time. This contradicts a widely-acknowledge computational assumption [23]:

**Exponential Time Hypothesis (ETH):** There exists an $\epsilon > 0$ such that no algorithm solves 3SAT in time $2^{\epsilon n}$, where $n$ is the number of variables.

Regarding **Q2**, [15] shows that assuming FPT $\neq W[2]$, for any $r$ the Independent Dominating Set problem is not $r$-approximable $^2$ (in FPT time).

Among interesting problems for which **Q1** and **Q2** are worth being asked are Independent Set, Coloring and Dominating Set. They fit in the frame of

---

$^2$ Actually, the result is even stronger: it is impossible to obtain a ratio $r = g(k)$ for any function $g$. 
both Q1 and Q2 above: they are hard to approximate in polynomial time while
their approximability in subexponential or in parameterized time is still open.
Note that INDEPENDENT SET and DOMINATING SET are moderately exponential
approximable within any ratio $1 - \varepsilon$, for any $\varepsilon > 0$ [5, 6], while COLORING is
approximable within ratio $(1 + 1/\chi(G))$, where $\chi(G)$ denotes the chromatic
number of a graph $G$ in moderately exponential time [3, 4].

Our contribution in this paper is to establish a link between a major con-
jecture in PCP theorem and inapproximability in subexponential-time and in
FPT-time, assuming ETH. We first state the conjecture while the definition of
PCP is deferred to the next section.

Linear PCP Conjecture (LPC): $3\text{Sat} \in \text{PCP}_{1,1/2}[\log |\phi| + D, E]$, where
$|\phi|$ is the size of the $3\text{Sat}$ instance (sum of lengths of clauses), $D$ and $E$
are constant.

Unlike ETH which is arguably recognized as a valid statement, LPC is a wide
open question. In the emphasized statement given just below, we claim that if
LPC turns out to hold, it immediately implies that one of the most interesting
questions in subexponential and parameterized approximation is negatively an-
swered. In particular, as shown in the sequel, assuming ETH the followings hold
for INDEPENDENT SET on $n$ vertices, for any constant $0 < r < 1$:
(i) There is no $r$-approximation algorithm in time $O(2^{n^{1-\varepsilon}})$ for any $\delta > 0$.
(ii) There is no $r$-approximation algorithm in time $O(2^{o(n)})$ if LPC holds.
(iii) There is no $r$-approximation algorithm in time $O(f(k)n^{O(1)})$ if LPC holds.

Remark that (i) is not conditional upon LPC. In fact, this is an immediate
consequence of near-linear PCP construction achieved in [13]. Note that similar
inapproximability results under ETH for $\text{Max-3Sat}$ and $\text{Max-3Lin}$ for some
subexponential running time have been obtained in [28].

In the following, Section 2 reviews some known consequences of near-linear
PCP. In Section 3, we show how a combination of two classic reductions yields pa-
rameterized inapproximabiliy bounds for $\text{INDEPENDENT SET}$ provided that LPC
and ETH hold (point (iii) above); we also provide a parameterized approxima-
tion preserving reduction that allows to transfer parameterized inapproximabil-
ity results to $\text{DOMINATING SET}$. In Section 4, we analyze known reductions in
the view of inapproximability in subexponential running time and present some
results similar to (i) and (ii).

2 Preliminaries

2.1 PCP and inapproximability of $\text{MAX-3SAT}$

A problem is in PCP$_{\alpha,\beta}[q,p]$ if there exists a PCP verifier which uses $q$ random
bits, reads at most $p$ bits in the proof and is such that:

- if the instance is positive, then there exists a proof such that V(erator)
  accepts with probability at least $\alpha$;
if the instance is negative, then for any proof $V$ accepts with probability at most $\beta$.

Based upon the above definition, the following theorem is proved in [13] (see also Theorem 7 in [28]), presenting a further refinement of the characterization of NP.

**Theorem 1.** [13] For every $\epsilon > 0$,

$$3\text{Sat} \in \text{PCP}_{1,\epsilon}[(1 + o(1)) \log n + O(\log(1/\epsilon)), O(\log(1/\epsilon))]$$

A recent improvement [28] of Theorem 1 (a PCP Theorem with two-query projection tests, sub-constant error and almost-linear size) has some important corollaries in polynomial approximation. Among those, the following two are of particular interest in what follows.

**Corollary 1.** [28] Under ETH, for every $\epsilon > 0$, and $\delta > 0$, it is impossible to distinguish between instances of MAX-3-LIN with $m$ equations where at least $(1 - \epsilon)m$ are satisfiable from instances where at most $(1/2 + \epsilon)m$ are satisfiable, in time $O(2^{m^{1-\delta}})$.

**Corollary 2.** [28] Under ETH, for every $\epsilon > 0$, and $\delta > 0$, it is impossible to distinguish between instances of MAX-3SAT with $m$ clauses where at least $(1 - \epsilon)m$ are satisfiable from instances where at most $(7/8 + \epsilon)m$ are satisfiable, in time $O(2^{m^{1-\delta}})$.

The following is a stronger version of Corollary 2: it holds if LPC holds. This will be our working hypothesis.

**Hypothesis 1** Under ETH, there exists $r < 1$ such that: for every $\epsilon > 0$ it is impossible to distinguish between instances of MAX-3SAT with $m$ clauses where at least $(1 - \epsilon)m$ are satisfiable from instances where at most $(r + \epsilon)m$ are satisfiable, in time $2^{o(m)}$.

Using the well known sparsification lemma (Lemma 1), which intuitively allows to work with 3-SAT formula with linear lengths (the sum of the lengths of clauses is linearly bounded in the number of variables), a very standard argument gives the validity of Hypothesis 1 under LPC, see Lemma 2.

**Lemma 1.** [23] For all $\epsilon > 0$, a 3-SAT formula $\phi$ on $n$ variables can be written as the disjunction of at most $2^c n$ 3-SAT formula $\phi_i$ on (at most) $n$ variables such that $\phi_i$ contains each variable in at most $c_\epsilon$ clauses for some function $c_\epsilon$. Moreover, this reduction takes at most $p(n)2^c n$ time.

**Lemma 2.** If LPC\(^3\) holds, then Hypothesis 1 also holds.

\(^3\)Note that LPC as expressed in this article implies that Hypothesis 1 holds event with replacing $(1 - \epsilon)m$ by $m$. However, we define Hypothesis 1 with this lighter statement $(1 - \epsilon)m$ in order, in particular, to emphasize the fact that perfect completeness is not required in the LPC conjecture.
Proof. Suppose that $3\text{Sat} \in \text{PCP}_{1,1/2}[\log |\phi| + D, E]$, where $|\phi|$ is the sum of the lengths of clauses in the $3\text{Sat}$ instance, $D$ and $E$ are constants.

Given an $\epsilon > 0$, let $\epsilon'$ such that $0 < \epsilon' < \epsilon$. Given an instance $\phi$ of $3\text{Sat}$ on $n$ variables, we apply the sparsification lemma (with $\epsilon'$) to get $2^{\epsilon' n}$ instances $\phi_i$ on at most $n$ variables. Since each variable appears at most $c\epsilon'$ times in $\phi_i$, the global size of $\phi_i$ is $|\phi_i| \leq c\epsilon'n$.

Then for each formula $\phi_i$ we use the previous PCP assumption. The size of the proof is at most $E2^{|R|} = \epsilon'|\phi_i| \leq cn$ for some constants $\epsilon', c$ that depend on $\epsilon'$ (where $|R| = \log n + D$ is the number of random bits) since $E2^{|R|}$ is the total number of bits that we read in the proof. Take one variable for each bit in the proof: $x_1, \ldots, x_{cn}$. For each random string $R$, take all the $2^E$ possibilities for the $E$ variables read, and write a CNF formula which is satisfied if and only if the verifier accepts. This can be done with a formula with a constant number of clauses, say $C_1$, each clause having a constant number of variables, say $C_2$ ($C_1$ and $C_2$ depends on $E$).

If we consider the CNF formed by all these CNFs for all the random clauses, we get a CNF with $C_12^{|R|}$ clauses on variables $x_1, \ldots, x_{cn}$. The clauses are on $C_2$ variables but by adding a constant number of variables we can replace a clause on $C_2$ variables by an equivalent set of clauses on 3 variables. This way we get a 3-CNF formula and multiply the number of variables and the number of clauses by a constant, so they are still linear in $n$. For each $R$ you have a set of say $C_1'$ clauses.

Suppose that we start from a satisfiable formula $\phi_i$. Then there exists a proof for which the verifier always accepts. By taking the corresponding values for the variables $x_i$, and extending it properly to the new variables $y$, all the clauses are satisfied.

Suppose that we start from a non satisfiable formula $\phi_i$. Then for any proof (i.e. any truth values of variables), the verifier rejects for at least half of the random strings. If the verifier rejects for a random string $R$, then in the set of clauses corresponding to this variable at least one clause is not satisfied. It means that among the $C_1'2^{|R|}$ clauses (total number of clauses), at least $1/2 \cdot 2^{|R|}$ are not satisfied, i.e. a fraction $1/(2C_1')$ of the clauses.

Then either $m = C_1'2^{|R|} = O(n)$ clauses are satisfiable, or at least $m/(2C_1')$ clauses are not satisfied by each assignment. Distinguishing between these sets in time $2^{o(m)}$ would determine whether $\phi_i$ is satisfiable or not in $2^{o(n)}$. Doing this for each $\phi_i$ would solve $3\text{Sat}$ in time $p(n)2^{\epsilon'n}2^{\epsilon'n}O(2^{o(n)}) = O(2^{cn})$ (where $p$ is a polynomial). This is valid for any $\epsilon > 0$ so it would contradicting ETH.

Dealing with Independent Set, it is easy to see that, for any increasing and unbounded function $r(n)$, the problem is approximable within ratio $1/r(n)$ in subexponential time (recall that ratios $n^{r-1}$ are very unlikely to be achieved in polynomial time). Indeed, simply consider all the subsets of $V$ of size at most $n/r(n)$ and return the largest independent set among these sets. If a maximum independent set has size at most $n/r(n)$ then the algorithm finds it, otherwise the algorithm outputs a solution of size $n/r(n)$, while the size of an optimum
solution is at most $n$. The running time of the algorithm is $O^\ast\left(\binom{n}{r(n)}\right)$ that is subexponential in $n$.

Let us note that \textsc{Independent Set} has the so called self-improvement property \cite{22} claiming, roughly speaking, that either it is polynomially approximable by a polynomial time approximation schema, or no polynomial algorithm exists that guarantees some constant approximation ratio, unless $P = NP$.

With a similar proof, the above self-improvement property can be proved for \textsc{Independent Set} also in the case of parameterized approximation.

\textbf{Lemma 3.} \cite{17} The following statements are equivalent for \textsc{Independent Set}:

- there exists $r \in (0,1)$ such that there exists an $r$-approximation parameterized algorithm;
- for any $r \in (0,1)$ there exists an $r$-approximation parameterized algorithm.

\subsection{Expander Graphs}

\textbf{Definition 1.} A graph $G$ is a $(n,d,\alpha)$-expander graph if (i) $G$ has $n$ vertices, (ii) $G$ is $d$-regular, (iii) all the eigenvalues $\lambda$ of $G$ but the largest one is such that $|\lambda| \leq \alpha d$.

\textbf{Fact 1.} For any $k \in \mathbb{N}^*$ and any $\alpha > 0$ there exists $d$ and a $(k^2,d,\alpha)$-expander graph. Moreover, $d$ depends only on $\alpha$, and this graph can be computed in polynomial time for every fixed $\alpha$.

This fact follows from the following lemmas.

\textbf{Lemma 4 \cite{20}, or Th. 8.1 in \cite{22}.} For every positive integer $k$, there exists a $(k^2,8,5\sqrt{2}/8)$-expander graph, computable in polynomial time.

If $G$ is a graph with adjacency matrix $M$, let us denote $G^k$ the graph with adjacency matrix $M^k$.

\textbf{Lemma 5 (Fact 1.2 in \cite{29}).} If $G$ is a $(n,d,\alpha)$-expander graph, then $G^k$ is a $(n,d^k,\alpha^k)$-expander graph.

\textbf{Proof.} $G^k$ is obviously $d^k$ regular, and the eigenvalues of $G^k$ are the eigenvalues of $G$ to the power of $k$. \hfill $\Box$

\textbf{Proof of Fact 1.} Take $\alpha > 0$ and let $p$ be the smallest integer such that $(5\sqrt{2}/8)^p \leq \alpha$. $G^p$ is as required. The proof of Fact 1 is completed. \hfill $\Box$

Let $G$ be a graph on $n$ vertices and $H$ be a $(n,d,\alpha)$-expander graph. Let $t$ be a positive integer. We build the graph $G'_t$ on $N = nd^{t-1}$ vertices: each vertex corresponds to a $(t-1)$-random walk $x = (x_1, \ldots, x_t)$ on $H$ (meaning that $x_1$ is chosen at random, and $x_{i+1}$ is chosen randomly in the set of neighbors of $x_i$), and two vertices $x = (x_1, \ldots, x_t)$ and $y = (y_1, \ldots, y_t)$ in $G'_t$ are adjacent iff $\{x_1, \ldots, x_t, y_1, \ldots, y_t\}$ is a clique in $G$.

\textbf{Theorem 2 (claims 3.15 and 3.16 in \cite{22}).} Let $G$ be a graph on $n$ vertices and $H$ be a $(n,d,\alpha)$-expander graph. If $b > 6\alpha$, then:
achieve approximation ratio is an enforcement of Corollary 2, is used.

reduction in [9] and a classic gap-creating reduction. imability bound can be proved. Its proof essentially combines the parameterized

Because Corollary 2 only avoids

It is shown in [9] that, under

We are now able to prove the gap amplification with linear size amplification.

**Theorem 3.** Let $G$ be a graph on $n$ vertices (for a sufficiently large $n$) and $a > b$ be two positive real numbers. Then for any real $r > 0$ one can build in polynomial time a graph $G_r$ such that:

- $G_r$ has $N \leq Cn$ vertices for $C$ independent of $G$ ($C$ may depend on $r$);
- If $\omega(G) \leq bn$ then $\omega(G_r) \leq b_r N$;
- If $\omega(G) \geq an$ then $\omega(G_r) \geq a_r N$;
- $b_r/a_r \leq r$.

**Proof.** Let $k = \lceil \sqrt{n} \rceil$. We modify $G$ by adding $k^2 - n$ dummy (isolated) vertices. Let $G'$ be the new graph. It has $n' = k^2$ vertices. Note that $n' \leq (\sqrt{n} + 1)^2 = n + 2\sqrt{n} + 1 = n + o(n)$. Let $n$ be such that $1 - \epsilon \leq n/n' \leq 1$ for a small $\epsilon$.

Thanks to Fact 1, we consider a $(k^2, d, \alpha)$-expander graph $H$ for a sufficiently small $\alpha$ (the value of which will be fixed later). According to Theorem 2 (applied on $G'$) we build in polynomial time a graph $G'_t$ on $N' = n'd^t$ vertices such that

- $\omega(G) \leq bn$ then $\omega(G') = \omega(G) \leq bn'$, hence $\omega(G'_t) \leq (b + 2\alpha)^t N$;
- $\omega(G) \geq an$ then $\omega(G') = \omega(G) \geq an'(1 - \epsilon)$, hence $\omega(G'_t) \geq (a(1 - \epsilon) - 2\alpha)^t N$.

We choose $\epsilon$ and $\alpha$ such that $a(1 - \epsilon) - 2\alpha > b + 2\alpha$, and then $t$ such that $(a(1 - \epsilon) - 2\alpha)^t/(b + 2\alpha)^t \leq r$. The number of vertices of $G'_t$ is clearly linear in $n$ (first point of the theorem). $b_r = (b + 2\alpha)^t$ and $a_r = (a(1 - \epsilon) - 2\alpha)^t$ fulfills items 2, 3 and 4. 

We prove a challenging question is to obtain a similar result for approximation algorithms for INDEPENDENT SET. In the sequel, we propose a reduction from MAX-3SAT to INDEPENDENT SET that, based upon the negative result of Corollary 2, only gives a negative result for some function $f$ (because Corollary 2 only avoids some subexponential running time). However, this reduction gives the desired inapproximability result if Hypothesis 1, which is an enforcement of Corollary 2, is used.

Based upon Hypothesis 1, the following theorem on parameterized inapproximability bound can be proved. Its proof essentially combines the parameterized reduction in [9] and a classic gap-creating reduction.

**Theorem 4.** Under Hypothesis 1 and ETH, for every $\epsilon > 0$, no parameterized approximation algorithm for INDEPENDENT SET running in time $f(k)N^{o(k)}$ can achieve approximation ratio $r + \epsilon$ in graphs of order $N$.
Proof. Suppose that such an algorithm exists for some $\epsilon > 0$. W.l.o.g., we can assume that $f$ is increasing, and that $f(k) \geq 2^k$. Take an instance $I$ of MAX-3SAT, let $K$ be an integer that will be fixed later, and do the following: Partition the $m$ clauses into $K$ groups $H_1, \ldots, H_K$ each of them containing, roughly, $m/K$ clauses each. Each group $H_i$ involves a number $s_i \leq 3m/K$ of variables. For all possible values of these variables, add a vertex in the graph $G_I$ if these values satisfy at least $\lambda m/K$ clauses in $H_i$ (the value of $\lambda$ will also be fixed later). Finally, add an edge between two vertices if they have one contradicting variable. In particular the vertices corresponding to the same group of clauses form a clique. It is easy to see that the so-constructed graph contains $N \leq K2^{3m/K}$ vertices.

The following easy claim holds.

Claim. If a variable assignment satisfies at least $\lambda m/K$ clauses in at most $s$ groups, then it satisfies at most $\lambda m + s(1-\lambda)m/K$ clauses.

Proof of claim. Consider an assignment as the one claimed in claim’s statement.

This assignment satisfies at most $m/K$ clauses in at most $s$ groups, and at most $\lambda m/K$ in the other $K-s$ groups, so in total at most $sm/K + (K-s)\lambda m/K = \lambda m + s(1-\lambda)m/K$, that completes the proof of the claim.

Now, let us go back to the proof of the theorem. Assume an independent set of size at least $t$ in $G_I$. Then one can achieve a partial solution that satisfies at least $\lambda m/K$ clauses in at least $t$ groups. So, at least $t\lambda m/K$ clauses are satisfiable. In other words, if at most $(r+\epsilon)m$ clauses are satisfiable, then a maximum independent set in $G_I$ has size at most $K^{\frac{r+\epsilon}{r}}$. Suppose that at least $(1-\epsilon)m$ clauses are satisfiable. Then, using Lemma 3, there exists a solution satisfying at least $\lambda m/K$ clauses in at least $K^{\frac{1-\epsilon}{1-\epsilon'}}$ groups; otherwise, it should be $\lambda m + s(1-\lambda)m/K < (1-\epsilon')m$. Then, there exists an independent set of size $K^{\frac{1-\epsilon}{1-\epsilon'}}$ in $G_I$.

Now, set $K = \lceil \phi(m)/(1-\epsilon^2) \rceil$ where $\phi$ is the inverse function of $f$ (i.e., $\phi = f^{-1}$). Set also $\lambda = 1-\epsilon$, and $\epsilon' = \epsilon^3$. Run the assumed $(r+\epsilon)$-approximation parameterized algorithm for INDEPENDENT SET in $G_I$ with parameter $k = (1-\epsilon^3)K$. Then, if at least $(1-\epsilon')m$ equations are satisfiable, there exists an independent set of size at least $K^{\frac{1-\epsilon'}{1-\epsilon'}}K = (1-\epsilon^3/\epsilon)K = (1-\epsilon^2)K = k$; so, the algorithm must output an independent set of size at least $(r+\epsilon)k$. Otherwise, if at most $(r+\epsilon)$ equations are satisfiable, the size of an independent set is at most $K^{\frac{r+\epsilon}{r}} = K^{\frac{r+\epsilon'}{r+\epsilon}} = k(1-\epsilon^3/(1-\epsilon)) = k(r + re + o(\epsilon'))$.

So, for $\epsilon$ sufficiently small, the algorithm allows to distinguish between the two cases of MAX-3SAT (for $\epsilon'$).

The running time of the yielded algorithm is $f(k)N^{o(k)}$, but $f(k) = f((1-\epsilon^2)K) = m$, and $N^{o(k)} = N^{k/\psi(k)}$ for some increasing and unbounded function $\psi$, and $N^{o(k)} = (K2^{3m/K})^{k/\psi(k)} = 2^{o(m)}$. □

Using Lemma 3 together with Theorem 4, the following result can be easily derived.
Corollary 3. Under Hypothesis 1 and ETH, for any \( r \in (0,1) \) there is no \( r \)-approximation parameterized algorithm for Independent Set (i.e., an algorithm that runs in time \( f(k)p(n) \) for some function \( f \) and some polynomial \( p \)).

Let us now deal with Dominating Set that is known to be W[2]-hard [14]. Existence of FPT-approximation algorithms for this problem is an open question [15]. Here, we present an approximation preserving reduction (fitting the parameterized framework) that works with the special set of instances produced in the proof of Theorem 4. This reduction will allow us to obtain a lower bound (based on the same hypothesis) for the approximation of Min Dominating Set from Theorem 4.

Consider a graph \( G(V,E) \) on \( n \) vertices where \( V \) is a set of \( K \) cliques \( C_1, \ldots, C_K \). We build a graph \( G'(V',E') \) such that \( G \) has an independent set of size \( \alpha \) if and only if \( G' \) has a dominating set of size \( 2K - \alpha \). The graph \( G' \) is built as follows. For each clique \( C_i \) in \( G \), add a clique \( C_i' \) of the same size in \( G' \). Add also: an independent set \( S_i \) of size \( 3K \), each vertex in \( S_i \) being adjacent to all vertices in \( C_i' \) and a special vertex \( t_i \) adjacent to all the vertices in \( C_i' \). For each edge \( e = (u,v) \) with \( u \) and \( v \) not in the same clique in \( G \), add an independent set \( W_e \) of size \( 3K \). Suppose that \( u \in C_i \) and \( v \in C_j \). Then, each vertex in \( W_e \) is linked to \( t_i \) and to all vertices in \( C_j' \) but \( u \) (and \( t_j \) and all vertices in \( C_j' \) but \( v \)).

Informally, the reduction works as follows. The set \( S_i \) ensures that we have to take at least one vertex in each \( C_i' \), the fact that \( |W_e| = 3K \) ensures that it is never interesting to take a vertex in \( W_e \). If we take vertex \( t_i \) in a dominating set, this will mean that we do not take any vertex in the set \( C_i \) in the corresponding independent set in \( G \). If we take one vertex in \( C_j' \) (but not \( t_j \)), this vertex will be in the independent set in \( G \). Let us state this property in the following lemma.

Lemma 6. \( G \) has an independent set of size \( \alpha \) if and only if \( G' \) has a dominating set of size \( 2K - \alpha \).

Proof. Suppose that \( G \) has an independent set \( S \) of size \( \alpha \). Then, \( S \) has one vertex in \( \alpha \) sets \( C_i \), and no vertex in the other \( K - \alpha \) sets. We build a dominating set \( T \) in \( G' \) as follows: for each vertex in \( S \) we take its copy in \( G' \). For each clique \( C_i \) without vertices in \( S \), we take \( t_i \) and one (anyone) vertex in \( C_i' \). The dominating set \( T \) has size \( \alpha + 2(K - \alpha) = 2K - \alpha \). For each \( C_i' \) there exists a vertex in \( T \); so, vertices in \( C_i' \) \( t_i \) and vertices in \( S_i \) are dominated. Now take a vertex in \( W_e \) with \( e = (u,v) \), \( u \in C_i \) and \( v \in C_j \). If \( C_i \cap S = \emptyset \) (or \( C_j \cap S = \emptyset \)), then \( t_i \in T \) (or \( t_j \in T \) and, by construction, \( t_i \) is adjacent to all vertices in \( W_e \)). Otherwise, there exist \( w \in S \cap C_i \) and \( x \in S \cap C_j \). Since \( S \) is an independent set, either \( w \neq u \) or \( x 
eq v \). If \( w \neq u \), by construction \( w \) (its copy in \( C_i' \)) is adjacent to all vertices in \( W_e \) and, similarly, for \( x \) if \( x \neq v \). So, \( T \) is a dominating set.

Conversely, suppose that \( T \) is a dominating set of size \( 2K - \alpha \). Since \( S_i \) is an independent set of size \( 3K \), we can assume that \( T \cap S_i = \emptyset \) and the same occurs with \( W_e \). In particular, there exists at least one vertex in \( T \) in each \( C_i \). Now, suppose that \( T \) has two different vertices \( u \) and \( v \) in the same \( C_i \). Then we can replace \( v \) by \( t_i \) getting a dominating set (vertices in \( S_i \) are still dominated by \( u \), and any vertex in some \( W_e \) which is adjacent to \( v \) is adjacent to \( t_i \)). So, we can
assume that \( T \) has the following form: exactly one vertex in each \( C_i \), and \( K - \alpha \) vertices \( t_i \). Hence, there are \( \alpha C_i \) cliques where \( t_i \) is not in \( T \). We consider in \( G \) the set \( S \) constituted by the \( \alpha \) vertices in \( T \) in these \( \alpha \) sets. Take two vertices \( u, v \) in \( S \) with, say, \( u \in C_i \) and \( v \in C_j \) (with \( t_i \not\in T \) and \( t_j \not\in T \)). If there were an edge \( e = (u, v) \) in \( G \), neither \( u \) nor \( v \) would have dominated a vertex in \( W_e \) (by construction). Since neither \( t_i \) nor \( t_j \) is in \( T \), this set would not have been a dominating set, a contradiction. So \( S \) is an independent set.

**Theorem 5.** Under Hypothesis 1 and ETH, for every \( \epsilon > 0 \), no approximation algorithm running in time \( f(k)N^{\omega(k)} \) can achieve approximation ratio smaller than \( 2 - r - \epsilon \) for Dominating Set in graphs of order \( N \).

**Proof.** In the proof of Theorem 4, we produce a graph \( G_I \) which is made of \( K \) cliques and such that: if at least \( (1 - \epsilon)m \) clauses are satisfiable in \( I \), then there exists an independent set of size \((1 - O(\epsilon))K\); otherwise (at most \((r + \epsilon)m\) clauses are satisfiable in \( I \)), the maximum independent set has size at most \((r + O(\epsilon))K\). The previous reduction transforms \( G_I \) in a graph \( G'_I \) such that, applying Lemma 6, in the first case there exists a dominating set of size at most \( 2K - (1 - O(\epsilon))K = K(1 + O(\epsilon)) \) while, in the second case, the size of a dominating set is at least \( 2K - (r + O(\epsilon))K = K(2 - r - O(\epsilon)) \). Thus, we get a gap with parameter \( k' = K(1 + O(\epsilon)) \). Note that the number of vertices in \( G'_I \) is \( N' = N + K + 3K + 3K|E_I| = O(N^3) \) (where \( E_I \) is the set of edges in \( G_I \)). If we were able to distinguish between these two sets of instances in time \( f(k')N^{\omega(k')} \), this would allow to distinguish the corresponding independent set instances in time \( f(k')N^{\omega(k')} = g(k)N^\omega(k) \) since \( k' = K(1 + O(\epsilon)) = k(1 + O(\epsilon)) \) \((k = K(1 - \epsilon^3)) \) being the parameter chosen for the graph \( G_I \).

Such a lower bound immediately transfers to Set Cover since a graph on \( n \) vertices for Dominating Set can be easily transformed into an equivalent instance of Set Cover with ground set and set system both of size \( n \).

**Corollary 4.** Under Hypothesis 1 and ETH, for every \( \epsilon > 0 \), no approximation algorithm running in time \( f(k)m^{\omega(k)} \) can achieve approximation ratio smaller than \( 2 - r - \epsilon \) for Set Cover in instances with \( m \) sets.

4 On the approximability of Independent Set and related problems in subexponential time

As mentioned in Section 2, an almost-linear size PCP construction \([28]\) for 3Sat allows to get the negative results stated in Corollaries 1 and 2. In this section, we present further consequences of Theorem 1, based upon a combination of known reductions with (almost) linear size amplifications of the instance.

First, Theorem 1 combined with the reduction in \([1]\) showing inapproximability results for Independent Set in polynomial time, leads to the following result.
Theorem 6. Under ETH, for any $r > 0$ and any $\delta > 0$, there is no $r$-approximation algorithm for Independent Set running in time $O(2^{N^{1-\delta}})$, where $N$ is the size of the input graph for Independent Set.

Proof. Given an $\epsilon > 0$, let $\epsilon'$ such that $0 < \epsilon' < \epsilon$. Given an instance $\phi$ of 3SAT on $n$ variables, we first apply the sparsification lemma (with $\epsilon'$) to get $2^{\epsilon'n}$ instances $\phi_i$ on at most $n$ variables. Since each variable appears at most $c_{\epsilon'}$ times in $\phi$, the global size of $\phi_i$ is $|\phi_i| \leq c_{\epsilon'}n$.

Consider a particular $\phi_i$, $r > 0$ and $\delta > 0$. We use the fact that $3\text{SAT} \in \text{PCP}_{1,r}((1+o(1))) \log |\phi| + D_r, E_r$ (where $D_r$ and $E_r$ are constants that depend only on $r$), in order to build the following graph $G_{\phi_i}$ (see also [1]). For any random string $R$, and any possible value of the $E_r$ bits read by $V$, add a vertex in the graph if $V$ accepts. If two vertices are such that they have at least one contradicting bit (they read the same bit which is 1 for one of them and 0 for the other one), add an edge between them. In particular, the set of vertices corresponding to the same random string is a clique.

Assume that $\phi_i$ is satisfiable. Then there exists a proof for which the verifier accepts for any random string $R$. Take for each random string $R$ the vertex in $G_{\phi_i}$ corresponding to this proof. There is no conflict (no edge) between any of these $2^{|R|}$ vertices, hence $\alpha(G_{\phi_i}) = 2^{|R|}$ (where, in a graph $G$, $\alpha(G)$ denotes the size of a maximum independent set).

If $\phi_i$ is not satisfiable, then $\alpha(G_{\phi_i}) \leq r2^{|R|}$. Indeed, suppose that there is an independent set of size $\alpha > r2^{|R|}$. This independent set corresponds to a set of bits with no conflict, defining part of a proof that we can arbitrarily extend to a proof $\Pi$. The independent set has $\alpha$ vertices corresponding to $\alpha$ random strings (for which $V$ accepts), meaning that the probability of acceptance for this proof $\Pi$ is at least $\alpha/2^{|R|} > r$, a contradiction with the property of the verifier.

Furthermore, $G_{\phi_i}$ has $N \leq 2^{|R|}2^{E_r} \leq C' |\phi_i|^{1+o(1)} = Cn^{1+o(1)}$ vertices (for some constants $C, C'$ that depend on $\epsilon'$) since $|\phi_i| \leq c_{\epsilon'}n$. Then, one can see that, for any $r' > r$, an $r'$-approximation algorithm for Independent Set running in time $O(2^{N^{1-\delta'}})$ would allow to decide whether $\phi_i$ is satisfiable or not in time $O(2^{n^{1-\delta'}})$ for some $\delta' < \delta$. Doing this for each of the formula $\phi_i$ would allow to decide whether $\phi$ is satisfiable or not in time $p(n)2^{\epsilon'n} + 2^{\epsilon'n}O(2^{n^{1-\delta'}}) = O(2^{\epsilon'n})$ (where $p$ is a polynomial). This is valid for any $\epsilon > 0$ so it would contradicting ETH.

Since (for $k \leq N$), $N^{k^{1-\delta}} = O(2^{N^{1-\delta'}})$, for some $\delta' < \delta$, the following result also holds.

Corollary 5. Under ETH, for any $r > 0$ and any $\delta > 0$, there is no $r$-approximation algorithm for Independent Set (parameterized by $k$) running in time $O(N^{k^{1-\delta}})$, where $N$ is the size of the input graph.

The results of Theorem 6 and Corollary 5 can be immediately extended to problems that are linked to Independent Set by approximability preserving reductions (that preserve at least constant ratios) and have linear amplifications of the sizes of the instances.
Proposition 1. Under ETH, for any \( q > 0 \) and any \( \delta > 0 \), there is no \( r \)-approximation algorithm for either Set Packing or Bipartite Subgraph running in time \( O(2^{n^{1-\delta}}) \) in a graph of order \( n \).

Proof. Consider the following reduction from Independent Set to Bipartite Subgraph ([30]). Let \( G(V,E) \) be an instance of Independent Set of order \( n \). Construct a graph \( G'(V',E') \) for Bipartite Subgraph by taking two distinct copies of \( G \) (denote them by \( G_1 \) and \( G_2 \), respectively) and adding the following edges: a vertex \( v_i \) of copy \( G_1 \) is linked with a vertex \( v_j \) of \( G_2 \), if and only if either \( i = j \) or \( (v_i,v_j) \in E \). \( G' \) has \( 2n \) vertices. Let now \( S \) be an independent set of \( G \). Then, obviously, taking the two copies of \( S \) in \( G_1 \) and \( G_2 \) induces a bipartite graph of size \( 2|S| \). Conversely, consider an induced bipartite graph in \( \tilde{G}' \) of size \( t \), and take the largest among the two color classes. By construction it corresponds to an independent set in \( G \), whose size is at least \( t/2 \) (note that it cannot contain 2 copies of the same vertex). So, any \( r \)-approximate solution for Bipartite Subgraph in \( G' \) can be transformed into an \( r \)-approximate solution for Independent Set in \( G \). Observe finally that the size of \( G' \) is two times the size of \( G \). 

\( \square \)

Dealing with minimization problems, Theorem 6 and Corollary 5 can be extended to Coloring, thanks to the reduction given in [24].

Given a graph \( G \) whose vertex set is partitioned into \( K \) cliques each of size \( S \), and given a prime number \( q > S \), a graph \( H_q \) having the following properties can be built in polynomial time: (i) the vertex set of \( H_q \) is partitioned into \( q^2K \) cliques, each of size \( q^3 \); (ii) \( \alpha(H_q) \leq \max\{q^2\alpha(G);q^2(\alpha(G)-1)+K; qK\} \); (iii) if \( \alpha(G) = K \), then \( \chi(H_q) = q^3 \).

Note that this reduction uses the particular structure of graphs produced in the inapproximability result in [1] (as in Theorem 6). Then, we deduce the following result.

Proposition 2. Under ETH, for any \( r > 1 \) and any \( \delta > 0 \), there is no \( r \)-approximation algorithm for Coloring running in time \( O(2^{n^{1-\delta}}) \) in a graph of order \( n \).

Proof. Fix a ratio \( r > 1 \), and let \( r_{IS} > 0 \) be such that \( r_{IS}^2 + r_{IS}^2 < 1/r \). Start from the graph \( G_{\phi} \), produced in the proof of Theorem 6 for ratio \( r_{IS} \). The vertex set of \( G_{\phi_i} \) is partitioned into \( K = 2^{|R|} \) cliques, each of size at most \( 2^E \). By adding dummy vertices (a linear number, since \( E_r \) is a fixed constant), we can assume that each clique has the same size \( S = 2^E r \), so the number of vertices in \( G_{\phi_i} \) is \( N = KS = 2^{|R|} 2^E r \).

Let \( q > \max\{S,1/r_{IS}\} \) be a prime number, and consider the graph \( H_q \) produced from \( G_{\phi_i} \) by the reduction in [24] mentioned above. If \( \phi_i \) is satisfiable,
\(\alpha(G_{\phi}) = K\) and then by the third property of the graph \(H_q\), \(\chi(H_q) = q^3\). Otherwise, by the second property \(\alpha(H_q) \leq \max\{q^2\alpha(G_\phi); q^2(\alpha(G_\phi)-1) + K; qK\}\). Formula \(\phi_i\) being not satisfiable, \(\alpha(G_{\phi_i}) \leq r_{IS}K\). By the choice of \(q\), \(qK \leq q^2r_{IS}K\), so \(\alpha(H_q) \leq q^2r_{IS}K + K = (q^2r_{IS} + 1)K\). Since the number of vertices in \(H_q\) is \(Kq^5\), we get that \(\chi(H_q) \geq q^5/(q^2r_{IS} + 1)\). The gap created for the chromatic number in the two cases is then at least:

\[
\frac{q^5}{(q^2r_{IS} + 1)q^3} = \frac{1}{r_{IS} + 1/q^2} \geq \frac{1}{r_{IS} + r_{IS}^2} \geq r
\]

The result follows since \(H_q\) has \(Kq^5\) vertices and \(q\) is a constant (that depends only on the ratio \(r\) and on the constant number of bits \(p\) read by \(V\)), so the size of \(H_q\) is linear in the size of \(G_\phi\).

We consider the approximability of Vertex Cover and Min-Sat in subexponential time. The following statement provides a lower bound to such a possibility.

**Proposition 3.** Under ETH, for any \(r > 0\) and any \(\delta > 0\), there is no \((7/6 - \epsilon)\)-approximation algorithm for Vertex Cover running in time \(O(2^{N^{1-\epsilon}})\) in graphs of order \(N\), nor for Min-Sat running in time \(2^{m^{1-\delta}}\) in CNF formulae with \(m\) clauses.

**Proof.** We combine Corollary 1 with the following classical reduction. Consider an instance \(I\) of Max 3-Lin on \(m\) equations. Build the following graph \(G_I\):

- for any equation and any of the eight possible values of the 3 variables in it, add a vertex in the graph if the equation is satisfied;
- if two vertices are such that they have one contradicting variable (the same variable has value 1 for one vertex and 0 for the other one), then add an edge between them.

In particular, the set of vertices corresponding to the same equation is a clique. Note that each equation is satisfied by exactly 4 values of the variables in it. Then, the number of vertices in the graph is \(N = 4m\). Consider an independent set \(S\) in the graph \(G_I\). Since there is no conflict, it corresponds to a partial assignment that can be arbitrarily completed into an assignment \(\tau\) for the whole system. Each vertex in \(S\) corresponds to an equation satisfied by \(\tau\) (and \(S\) has at most one vertex per equation), so \(\tau\) satisfies (at least) \(|S|\) equations. Reciprocally, if an assignment \(\tau\) satisfies \(\alpha\) clauses, there is obviously an independent set of size \(\alpha\) in \(G_I\). Hence, if \((1 - \epsilon)m\) equations are satisfiable, there exists an independent set of size at least \((1 - \epsilon)m\), i.e., a vertex cover of size at most \(N - (1 - \epsilon)m = N(3/4 + \epsilon/4)\). If at most \((1/2 + \epsilon)m\) equations are satisfiable, then each vertex cover has size at least \(N - (1/2 + \epsilon)m = N(7/8 - \epsilon/4)\).

We now handle Min-Sat problem via the following reduction (see [25]). Given a graph \(G\), build the following instance on Min-Sat. For each edge \((v_i, v_j)\) add a variable \(x_{ij}\). For each vertex \(v_i\) add a clause \(c_i\). Variable \(x_{ij}\) appears positively in \(c_i\) and negatively in \(c_j\). Then, take a vertex cover \(V^*\) of size \(k\); for any \(x_{ij}\)
fix the variable to true if \( v_i \in V^* \), to false otherwise. Consider a clause \( c_j \) with \( v_j \notin V^* \). If \( \overline{x_{ij}} \) is in \( c_j \) then \( v_i \) is in \( V^* \) hence \( x_{ij} \) is true; if \( x_{ji} \) is in \( c_j \) then, by construction, \( x_{ji} \) is false. So \( c_j \) is not satisfied, and the assignment satisfies at most \( k \) clauses. Conversely, consider a truth assignment that satisfies \( k \) clauses \( c_{i_1}, \ldots, c_{i_k} \). Consider the vertex set \( V^* = \{ v_{i_1}, \ldots, v_{i_k} \} \). For an edge \((v_i, v_j)\), if \( x_{ij} \) is set to true then \( c_i \) is satisfied and \( v_i \) is in \( V^* \), otherwise \( c_j \) is satisfied and \( v_j \) is in \( V^* \), so \( V^* \) is a vertex cover of size \( k \). Since the number of clauses in the reduction equals the number of vertices in the initial graph, the result is concluded.

All the results given in this section are valid under ETH and rule out some ratio in subexponential time of the form \( 2^{n^{1-\delta}} \). It is worth noticing that if LPC holds, then all these result would hold for any subexponential time.

**Corollary 6.** If LPC holds, under ETH the negative results of Theorem 6 and Propositions 1, 2 and 3 hold for any time complexity \( 2^{o(n)} \).

**Proof.** Using LPC, the same proof as in Theorem 6 creates for each \( \phi_i \) a graph on \( N = O(n) \) variables with either an independent set of size \( \alpha N \) (if \( \phi_i \) is satisfiable) or a maximum independent set of size at most \( \alpha/2N \) (if \( \phi_i \) is not satisfiable). Then using expander graphs, Theorem 3 allows to amplify this gap from 1/2 to any constant \( r > 0 \) while preserving the linear size of the instance. Results for the other problems immediately follow from the same arguments as above.

## 5 Conclusion

This paper presents conditional lower bounds of approximation ratio in FPT- and subexponential-time. Assuming ETH, we prove inapproximability in time \( 2^{n^{1-\delta}} \) for any \( \delta > 0 \) for the problems such as: **Independent Set**, **Set Packing**, **Bipartite Subgraph**, **Coloring**, **Vertex Cover**. If Linear PCP Conjecture turns out to hold, even in time \( 2^{o(n)} \) we cannot approximate any better. Also assuming ETH, we proved that Linear PCP Conjecture implies FPT-time inapproximability of **Independent Set** (for any ratio) and **Dominating Set** (for some ratio).

Our effort in this paper is only a first step and we wish to motivate further research. There remains a range of problems to be tackled, among which we propose the followings.

- Our inapproximability results, in particular those in FPT-time, are conditional upon Linear PCP Conjecture. Is it possible to relax the condition to a more plausible one?
- Or, we dare ask whether (certain) inapproximability results in FPT-time imply strong improvement in PCP theorem. For example, would the converse of Lemma 2 hold?

Note that we have considered in this article constant approximation ratios. In this sense, Theorem 6 is “tight” with respect to approximation ratios since, as
mentioned in Section 2, ratio $1/r(n)$ is achievable in subexponential time for any increasing and unbounded function $r$. However, dealing with parameterized approximation algorithms, achieving a non constant ratio is also an open question. More precisely, finding in FPT-time an independent set of size $g(k)$ when there exists an independent set of size $k$ is not known for any unbounded and increasing function $g$.

Finally, let us note that, in the same vein of our work, [27] in his recent paper initiates a proof checking view of parameterized complexity, by proposing a parameterized PCP and by giving a parameterized PCP characterization of $W[1]$. Possible links between these two approaches are worth being investigated in future works.
