(October 4, 2018)

Abstract: Polarization properties of high energy photodisintegration of the deuteron are studied within the framework of the hard rescattering mechanism (HRM). In HRM, a quark of one nucleon knocked-out by the incoming photon rescatters with a quark of the other nucleon leading to the production of two nucleons with high relative momentum. Summation of all relevant quark rescattering amplitudes allows us to express the scattering amplitude of the reaction through the convolution of a hard photon-quark interaction vertex, the large angle p-n scattering amplitude and the low momentum deuteron wave function. Within HRM, it is demonstrated that the polarization observables in hard photodisintegration of the deuteron can be expressed through the five helicity amplitudes of NN scattering at high momentum transfer. At 90° CM scattering HRM predicts the dominance of the isovector channel of hard pn rescattering, and it explains the observed smallness of induced, $P_\theta$ and transferred, $C_z$ polarizations without invoking the argument of helicity conservation. Namely, HRM predicts that $P_\theta$ and $C_z$ are proportional to the $\phi_b$ helicity amplitude which vanishes at $\theta_{cm} = 90^\circ$ due to symmetry reasons. HRM predicts also a nonzero value for $C_z$ in the helicity-conserving regime and a positive $\Sigma$ asymmetry which is related to the dominance of the isovector channel in the hard reinteraction. We extend our calculations to the region where large polarization effects are observed in $pp$ scattering as well as give predictions for angular dependences.

I. INTRODUCTION

Hard photodisintegration of the deuteron provides a unique tool for studying the role of quarks and gluons in nuclear interactions. During the last decade several experiments have been performed [1–6] which indicated strongly the importance of quark-gluon degrees of freedom in these reactions starting at $E_\gamma \geq 1$ GeV.

First QCD based predictions for high momentum transfer photodisintegration of the deuteron were done within minimal Fock component approximation [7,8] in which it is assumed that only minimal number of partonic constituents dominate in large angle hard two-body scattering. Within this approximation the energy dependences of the set of fixed angle hard two-body reactions can be predicted according to the counting rule: $\frac{d\sigma}{dt} \sim s^{-(n_1+n_2+n_3+n_4-2)}$, in which $n_i$ is the number of fundamental constituents in the particle $i$ which is involved in the reaction. This prediction has been confirmed experimentally practically for all two-body reactions for fixed angle hard scattering kinematics in which $-t, -u \geq 2$ GeV$^2$.

For high momentum transfer $\gamma + d \rightarrow p + n$ reaction the above counting rule predicts an energy dependence, $\sim s^{-11}$ [9], which was confirmed experimentally for photon energies starting at 1 GeV [1–3].

The minimal Fock component approximation can be proven rigorously within perturbative QCD (pQCD) in which the masses of interacting current quarks are neglected. Thus the experimental success of the minimal Fock component approximation raised the expectations that the observed energy dependences indicate the onset of pQCD regime. This was an important question since there were several arguments [10,11] against the application of pQCD in the considered energy range as well as the attempts to describe the absolute cross sections of hard two-body exclusive reactions within leading twist pQCD have been largely unsuccessful (see e.g. [12,13]) underestimating the observed cross sections by several orders of magnitude $^1$.

Since, in QCD the interaction is realized through the exchange of vector gluons, in pQCD (due to vanishing quark masses) the helicity of interacting particles should be conserved. Therefore as an independent check of the onset of pQCD one can investigate the effects of hadronic helicity conservation (HHC).

The experiments which are aimed at the studies of polarization observables in hard reactions are best suited for HHC studies. The first experiments were performed for elastic $pp$ scattering. While in wide range of hard scattering kinematics the $pp$ data generally are in agreement with HHC, in some instances the striking disagreement is observed [15]. For example in $\vec{p} + \vec{p} \rightarrow p + p$ scattering at $\theta_{cm} = 90^\circ$ and $P_{Lab} = 11.75$ GeV [15] the measurements demonstrated that protons polarized transverse to the scattering plane have four times larger probability to scatter with spins parallel than antiparallel to each other. This number is considerably larger than HHC predication of two [17,18]. Several theoretical approaches have been proposed to describe the observed enhancement of the polarization effects (see e.g. [17–21]) however the exper-

---

$^1$The smallness of the calculated cross sections does not rule out completely the relevance of pQCD regime, since one may expect a sizable effects from unaccounted hidden color component of hadronic wave functions [14].
The deuteron wave function, hard photon-quark interaction in the deuteron. This assumption allows us to express a hard rescattering with a quark of the second nucleon quark from one nucleon in the deuteron which then makes photodisintegration of the deuteron proceeds through (HRM) [24]. HRM is based on the assumption that hard within the recently developed model of hard rescattering in hard photodisintegration reaction of the deuteron [5,16].

We expect a wealth of the new data within next several years. Within HRM we calculate several polarization observables of deuteron photodisintegration is observed already at 1 GeV and 2 GeV and whose verification can advance our understanding the dynamics of hard photodisintegration.

\[ \langle \lambda_A, \lambda_B | A | \lambda_1, \lambda_D \rangle = \sum_{(\eta_1, \eta_2), (\xi_1, \xi_2), (\lambda_1, \lambda_2)} \int \psi_N^{\lambda_B, \eta_2}(p_B, x_2, k_{2\perp}) \bar{u}_{\eta_2}(p_B - k_2)[-igT_\gamma^F \gamma^\mu] \times \]

\[ i[u_\xi(p_1 - k_1 + q)\bar{u}_\xi(p_1 - k_1 + q)] \frac{1}{(1 - x_1)s'(\alpha_c - \alpha + i\varepsilon)}[\lambda(p_1 - k_1) - igT_\gamma^F \gamma^\mu]u_{\xi_1}(p_1 - k_1) \psi_N^{\lambda_1, \xi_1}(p_1, x_1, k_{1\perp}) \]

\[ \bar{u}_{\eta_1}(p_A - k_1)[-igT_\gamma^F \gamma^\mu]u_{\xi_2}(p_2 - k_2)\psi_N^{\lambda_2, \xi_2}(p_2, x_2, k_{2\perp}) \]

\[ G^{\mu, \nu}(r) \frac{dx_1}{x_1} \frac{d^2k_{1\perp}}{2(2\pi)^2} \frac{dx_2}{x_2} \frac{d^2k_{2\perp}}{2(2\pi)^2} \frac{\psi_{p_+}^{p_+, \lambda_1, \lambda_2}(\alpha, p_+)}{(1 - \alpha) - \alpha} \frac{d^2p_+}{2(2\pi)^3} \]

were the four-momenta: \( p_1, p_2, k_1, k_2, r, p_A \) and \( p_B \) are defined in Fig.1. Note that \( k_1 \) and \( k_2 \) define the four-momenta of residual quark-gluon system of the nucleons without specifying their actual composition. \( s' = s - M_A^2 \), where \( s = (q + p_d)^2 \). \( x_1, x_2, x_1' \) and \( x_2' \) are the light-cone momentum fractions of initial and final nucleons carried out by spectator system in the nucleons \( (x_1(2) = \frac{k_{1(2)} + p_{1(2)}}{p_{1(2)} + s'}, x_2'(2) = \frac{k_{2(2)} + p_{2(2)}}{p_{2(2)} + s'}) \). \( \alpha = \frac{p_2}{p_{2+}} \) is the light cone momentum fraction of the deuteron carried by one of the nucleons and \( p_{2+} \) is the relative transverse momentum of the nucleons in the deuteron. The denominator \( (1 - x_1)s'(\alpha_c - \alpha + i\varepsilon) \) is obtained from the denominator of knocked-out quark propagator, \( (p_1 - k_1 + q)^2 - m_q^2 + i\varepsilon \) by expressing it through \( \alpha \) and \( \alpha_c = 1 + \frac{1}{s'} \left[ \frac{m_q^2 - m_R^2(1 - x_1) + m^2_{\perp}x + (k_1 - xp_1)^2}{x_1(1 - x_1)} \right] \)

\[ \alpha \]

2The light cone four-momentum is defined as \( (p_+, p_-, p_{\perp}) \), where \( p_{\perp} = E \pm p_\perp \). Here the \( z \) axis is defined in the direction opposite to the incoming photon momentum.
where $m^2_N = p_{-d}+(1-\alpha) - p_d^2$ and $m^2_F = k_1 - (p_{d}+(1-\alpha)x_1 - k_{1\perp})$ are effective masses of the off-shell nucleon and its residual system respectively. $m_q$ represents the current quark mass of the knocked-out quark. The scattering process in Eq.(2) can be described through the combination of the following blocks: a) $\Psi_N^\lambda_1,\lambda_2,\lambda_3(\alpha,p_\perp)$, is the light-cone deuteron wave function which describes the transition of the deuteron with helicity $\lambda_D$ into two nucleons with $\lambda_1$ and $\lambda_2$ helicities respectively. b) The term in $\{\ldots\}_1$ describes the “knocking out” a $\xi_1$-helicity quark from the $\lambda_1$-helicity nucleon by an incoming photon with helicity $\lambda$. Subsequently, the “knocked-out” $\zeta_1$-helicity quark exchanges gluon, $([-igT^\kappa_\nu\gamma^\nu])$, with a quark from second nucleon producing a final $\eta_2$-helicity quark which enters the nucleon B with helicity $\lambda_B$. c) The term in $\{\ldots\}_2$ describes the emerging $\xi_2$-helicity quark from $\lambda_2$ - helicity nucleon which then exchanges a gluon, $([-igT^\kappa_\nu\gamma^\nu])$, with the knocked-out quark and produces a final $\eta_1$-helicity quark which enters the nucleon with helicity $\lambda_A$. d) The propagator of the exchanged gluon is $G^\kappa_\nu(r) = \frac{d^\kappa_\nu}{(ri\kappa_\nu)^2}$ with polarization matrix, $d^\kappa_\nu$, (fixed by light-cone gauge), and $r = (p_2 - k_2 + l) - (p_1 - k_1 + q)$, with $l = (p_B - p_2)$. In Eq.(2) the $\psi_N^\lambda$ represents everywhere a $\tau$-helicity single quark wave function of $\lambda$-helicity nucleon and $u_\tau$ is the quark spinor defined in the helicity basis. We keep only the $u_\xi u_\xi$ term in the numerator of the knocked-out quark propagator, since this is the only term that contributes through the soft (dominant) component of the deuteron wave function.

Next we integrate Eq.(2) by $\alpha$, taking into account only on-mass shell contribution of struck quark propagator, i.e. the second term in the decomposition: $(\alpha_\epsilon - \alpha + i\epsilon)^{-1} = P(\alpha_\epsilon - \alpha) - i\pi\delta(\alpha_\epsilon - \alpha)$. The on-mass shell approximation allows us to evaluate the photon-quark interaction vertex, for which, in vanishing current quark mass approximation one obtains:

$$u_\lambda(p_1 - k_1 + q)\langle[1 - ieq\gamma^\mu\gamma^\nu]|u_\xi(p_1 - k_1)\rangle = e_q\sqrt{2s} \times \sqrt{(1 - (1 - \alpha)(1 - x_1))(1 - \alpha)(1 - x_1)} \times \delta^\lambda_\lambda\delta^\lambda_\xi.$$  

(4)

Two important features of the above equation should be emphasized: i) an energetic photon selects only those quarks from a nucleon that have the same helicity that the photon has ($\zeta_1 = \lambda_1$); ii) the helicity of the initial quark is conserved after it was struck by incoming photon ($\zeta = \xi_1$). Inserting Eq.(4) into Eq.(2) and taking the $d\alpha$ integral by estimating it through the residue at the pole $\alpha = \alpha_e$ one obtains:

$$\langle\lambda_A,\lambda_B | A_Q | \lambda_\gamma,\lambda_D\rangle = \sum_{(n_1,n_2),(\zeta_1,\lambda_1,\lambda_2)} \int e_q\sqrt{2} \times \sqrt{(1 - (1 - \alpha_e)(1 - x_1))(1 - \alpha_e)(1 - x_1)} \times \psi_N^{\lambda_1,n_1}(p_B,x_1,k_1) \langle[1 - igT^\kappa_\nu\gamma^\nu]|u_\xi(p_1 - k_1 + q)\rangle \times$$

$$\times \frac{\psi_N^{\lambda_2,n_2}(p_B,x_1,k_1)}{1 - x_1} \times u_\lambda(p_1 - k_1 + q)\langle[1 - igT^\kappa_\nu\gamma^\nu]|u_\xi(p_A - k_1)\rangle \times$$

$$\times \psi_N^{\lambda_3,n_3}(p_B,x_1,k_1,1 - x_1)\times u_\lambda(p_A - k_1)\langle[1 - igT^\kappa_\nu\gamma^\nu]\rangle.$$  

(5)

One can relate the expression in $\{\ldots\}$ to the quark-interchange kernel of $NN$ interaction. Taking into account the fact that the deuteron wave function peaks strongly at $\alpha_e = \frac{1}{2}$ we approximate Eq.(5), choosing $\alpha_e = \frac{1}{2}$. In this case in $x_1 \rightarrow 0$ limit, which corresponds to the Feynman picture of hard scattering [25], Eq.(5) factorizes into the product of $\gamma$ – quark scattering vertex and quark-exchange amplitude of $NN$ scattering [24]. In the case of the minimal Fock component approximation, in which $x_1, (1 - x_1) \sim 1$ the factorization is correct up to the scaling function $f(\theta_{cm})$, with $f(\theta_{cm} = 90^\circ) \approx 1$ [24]. Using this factorization, for Eq.(5) one obtains:

$$\langle\lambda_A,\lambda_B | A_Q | \lambda_\gamma,\lambda_D\rangle = \sum_{(n_1,n_2),(\zeta_1,\lambda_1,\lambda_2)} \int \frac{e_qf(\theta_{cm})}{\sqrt{2s^2}} dx_1 \times$$

$$\times \langle\eta_2,\lambda_B | (\eta_1,\lambda_A|A_{QIM}^{(s,l^2)}|\lambda_1,\lambda_\gamma) |\lambda_2\xi_2\rangle \times \psi_N^{\lambda_2,\lambda_1,\lambda_\gamma}(\alpha_e,\perp)\langle[1 - igT^\kappa_\nu\gamma^\nu]|u_\lambda(p_1 - k_1 + q)\rangle \times$$

(6)

where $\langle\eta_2,\lambda_B | (\eta_1,\lambda_A|A_{QIM}^{(s,l^2)}|\lambda_1,\lambda_\gamma) |\lambda_2\xi_2\rangle$ is the quark-interchange kernel (with quark-i interacting with the photon) corresponding to the expression in $\{\ldots\}$ in Eq.(5). Here $|\eta,\lambda_\gamma\rangle$ represents $\eta$-helicity quark wave function of $\lambda$-helicity nucleon. Since the momenta of interacting quarks are large ($1 - x_1 \sim 1$) one can assume that the interfering quarks carry the helicities of a parent nucleons (i.e. $\eta = \lambda$). This allows us to express the scattering amplitude in Eq.(6) through the helicities of the photon, deuteron and nucleons as follows:

$$\langle\lambda_A,\lambda_B | A_Q | \lambda_\gamma,\lambda_D\rangle = \sum_{\lambda_2} \int \frac{e_f(\theta_{cm})}{\sqrt{2s^2}} dx_1 \times$$

$$\langle\lambda_A,\lambda_B | A_{QIM}^{(s,l^2)}|\lambda_1,\lambda_\gamma,\lambda_D\rangle \psi_N^{\lambda_2,\lambda_1,\lambda_\gamma}(\alpha_e,\perp)\langle[1 - igT^\kappa_\nu\gamma^\nu]|u_\lambda(p_1 - k_1 + q)\rangle \times$$

(7)

where $|\lambda_1,\lambda_2\rangle$ represents two nucleons having $\lambda_1$ and $\lambda_2$ helicities respectively. Note that $A_{QIM}^{(s,l^2)}$ in the above equation is weighted with the charge of the knocked-out quark $Q$, thus it can not be directly related to the quark interchange amplitude of $pn \rightarrow pn$ scattering.

To calculate the total scattering amplitude within HRM we sum all amplitudes of topologies of Fig.1. Identifying $\lambda_A$ and $\lambda_D$ with the helicities of proton and neutron respectively, one obtains:
\[ \langle p_{\lambda A}, n_{\lambda B} \mid A \mid \lambda_\gamma, \lambda_D \rangle = \sum_{i \in D} \left[ \langle p_{\lambda A}, n_{\lambda B} \mid A_{qi} \mid \lambda_\gamma, \lambda_D \rangle - \langle n_{\lambda B}, p_{\lambda A} \mid A_{qi} \mid \lambda_\gamma, \lambda_D \rangle \right] \]  
\[ \langle n_{\lambda B}, p_{\lambda A} \mid A_{qi} \mid \lambda_\gamma, \lambda_D \rangle \]  
(8)

where one sums valence quarks of the deuteron. This sum can be performed within the quark-interchange model of hadronic interactions, which allows us to represent the NN scattering amplitude as follows [18]:

\[ \langle a'b'\mid A\mid ab \rangle = \frac{1}{2} \langle a'b' \rangle \sum_{i=a, j=b} \left[ I_i I_j + \vec{\tau}_i \cdot \vec{\tau}_j \right] F_{i,j} (s,t) \langle ab \rangle \]  
(9)

where \( I_i \) and \( \tau_i \) are identity and Pauli matrices defined in \( SU(2) \) flavor (isospin) space of the interchanged quarks. The kernel, \( F_{i,j}(s,t) \) describes an interchange of \( i \) and \( j \) quarks\(^3\).

One can use Eq.(9) to calculate the quark-charge weighted QIM amplitude, \( \langle a'b'\mid A^Q\mid ab \rangle \), to obtain:

\[ \langle a'b'\mid A^Q\mid ab \rangle = \frac{1}{3} \langle a'b' \rangle \sum_{i=a, j=b} \left[ I_i I_j + \vec{\tau}_i \cdot \vec{\tau}_j \right] (Q_i + Q_j) F_{i,j} (s,t) \langle ab \rangle = (Q_u + Q_d) \langle a'b'\mid A\mid ab \rangle \frac{1}{3} \langle a'b' \rangle [a \mid A \rangle [b \rangle \]  
(10)

The above result can be understood qualitatively: since the number of \( u \) and \( d \) quarks in the deuteron are equal one has the same number of diagrams with knocked out \( u \) and \( d \) quarks. Using Eqs.(7,8) and (10) for \( \gamma d \rightarrow pn \) amplitude one obtains:

\[ \langle p_{\lambda A}, n_{\lambda B} \mid A \mid \lambda_\gamma, \lambda_D \rangle = \sum_{\lambda_2} f(\theta_{cm}) \times \frac{3\sqrt{2}^8}{\lambda_2} \times \left[ \langle p_{\lambda A}, n_{\lambda B} \mid A_{pm}(s,t_u) \mid p_{\lambda A}, n_{\lambda_2} \rangle + \langle p_{\lambda A}, n_{\lambda B} \mid A_{pm}(s,u_n) \mid p_{\lambda_2}, p_{\lambda B} \rangle \right] \]  
\[ \int \Psi_{\lambda D, \lambda_\gamma, \lambda_2}^\dagger (\alpha_c, p_{\perp}) \frac{d^2 p_{\perp}}{(2\pi)^2} \]  
(11)

where \( t_u = (p_B - \frac{1}{2} p_D)^2 \), \( u_n = (p_A - \frac{1}{2} p_D)^2 \) and \( A_{pm} \) is the helicity amplitude of \( pn \) scattering, which is factorized from the integral. In the factorization we take into account also the antisymmetry of the deuteron wave function with respect to \( p \leftrightarrow n \). This factorization is justified due to the fact that at \( \alpha_c = \frac{1}{2} \) the momenta involved in the integration, \( p_{\perp} \leq 300 \text{ MeV}/c \) are much smaller than the transferred momenta in the \( A_{pn} \) amplitude. For the same reason one can approximate the light-cone deuteron wave function that enters in Eq.(11) through rather well known nonrelativistic deuteron wave function [26,24]:

\[ \Psi_{\lambda D, \lambda_\gamma, \lambda_2} = (2\pi)^4 \Psi_{NR}^{\lambda D, \lambda_\gamma, \lambda_2} \sqrt{m}, \]

where \( \Psi_{NR}^{\lambda D, \lambda_\gamma, \lambda_2} = [u(k) + w(k)] \sqrt{1+2 |A_{pm}|} \), with \( u(k) \) and \( w(k) \) corresponding to the \( s- \) and \( d- \) waves normalized as \( \int [u(k)]^2 ([w(k)]^2) d^3 k = 1 \) and \( \xi_{\lambda D, \lambda_\gamma, \lambda_2}^\dagger \) represents the spin component of the wave function.

### III. Predictions for Polarization Observables

#### A: Definition of Observables

We will discuss several polarization observables of reaction (1) for which there are ongoing experimental investigations [6,16]. These are:

- **recoil-proton polarization** \( P_y \) which corresponds to the measurement of asymmetry in the spin component of the protons parallel / antiparallel to the direction of \( y = \vec{q} \times \vec{p}_d \) for the reaction with unpolarized photon and deuteron.

- **Transfered polarizations** \( C_{x'} \) and \( C_{z'} \), which correspond to the measurement of asymmetry in the spin component of the protons parallel / antiparallel to the directions of \( \vec{x}' = \vec{p}_d \times \vec{p}_f \) and \( \vec{y} \) respectively for the reaction with circularly polarized photons and unpolarized deuteron.

- **Cross section asymmetry** \( \Sigma \) for the reaction with linearly polarized photons

These observables are expressed through the helicity amplitudes \( \langle \lambda_p \lambda_n \mid A \mid \lambda_\gamma, \lambda_D \rangle \) as follows [22,27]:

\[ f(\theta) P_y = 2Im \sum_{i=1}^{3} \left[ F_i^\dagger F_{i[3]+} + F_i F_{i[3]-} \right] \]

\[ f(\theta) C_{x'} = 2Re \sum_{i=1}^{3} \left[ F_i^\dagger F_{i[3]_-} + F_i F_{i[3]+} \right] \]

\[ f(\theta) C_{z'} = \sum_{i=1}^{6} \left[ |F_i^\dagger|^2 - |F_i|^2 \right] \]

\[ f(\theta) \Sigma = -2Re \sum_{i=1}^{3} \left[ F_{1[3]+} F_{2[3]-} - F_{1[3]_-} F_{2[3]+} \right] \]

\[ -F_{1[3]+} F_{2[3]-} + F_{1[3]_-} F_{2[3]+} \]

\[ f(\theta) = \sum_{i=1}^{6} \sum_{\pm} |F_{i\pm}|^2 \]  
(12)

where \( F_{i\pm} = \langle \pm \mid A \mid 1, 2 - i \rangle \), for \( i = 1, 2, 3 \) and \( F_{i\pm} = \langle \pm \mid A \mid 1, 5 - i \rangle \), for \( i = 4, 5, 6 \).
B. HRM Predictions

Based on Eq. (11) one calculates the observables defined in Eq. (12) expressing them through the helicity amplitudes of \(pn\) scattering. Derivations are simplified further by using the fact that the momenta relevant in the deuteron wave function are \(\leq 300\) MeV/c. As a result one can restrict by \(s\) wave contribution in the deuteron wave function only. In this case the radial part of the deuteron wave function in Eq. (12) will cancel out and one obtains:

\[
P_y = -\frac{2 Im \left\{ \phi_1^3 \left[ 2 (\phi_1 + \phi_2) + \phi_3 - \phi_4 \right] \right\}}{2|\phi_1|^2 + 2|\phi_2|^2 + |\phi_3|^2 + |\phi_4|^2 + 6|\phi_5|^2}
\]

\[
C_{x'} = \frac{2 Re \left\{ \phi_1^3 \left[ 2 (\phi_1 - \phi_2) + \phi_3 + \phi_4 \right] \right\}}{2|\phi_1|^2 + 2|\phi_2|^2 + |\phi_3|^2 + |\phi_4|^2 + 6|\phi_5|^2}
\]

\[
C_{z'} = \frac{2 Re \left\{ |\phi_5|^2 - \phi_1^3 \phi_4 \right\}}{2|\phi_1|^2 + 2|\phi_2|^2 + |\phi_3|^2 + |\phi_4|^2 + 6|\phi_5|^2}
\]

\[
\Sigma = \frac{2 Re \left\{ |\phi_5|^2 - \phi_1 \phi_2 \phi_3 \right\}}{2|\phi_1|^2 + 2|\phi_2|^2 + |\phi_3|^2 + |\phi_4|^2 + 6|\phi_5|^2},
\]

where off-shell helicity amplitudes of \(pn\) scattering are:

\[
\phi_1 (s, t_n, u_n) = \langle +, + | A_{pn-pn} + A_{pn-np} | +, + \rangle
\]

\[
\phi_2 (s, t_n, u_n) = \langle +, + | A_{pn-pn} + A_{pn-np} | -, - \rangle
\]

\[
\phi_3 (s, t_n, u_n) = \langle +, - | A_{pn-pn} + A_{pn-np} | +, + \rangle
\]

\[
\phi_4 (s, t_n, u_n) = \langle +, - | A_{pn-pn} + A_{pn-np} | -, - \rangle
\]

Due to the relation: \(A_{pn-pn/np} = A_{I=1}^{s=0} + A_{I=0}^{s=0}\), in which \(I\) is the isospin of the \(pn\) system one observes that in the on-shell limit HRM predicts a dominance of the isovector channel in \(pn\) scattering at \(\theta_{cm} = 90^\circ\). In this case one has the following features of on-shell \(\phi\)-amplitudes at \(\theta_{cm} = 90^\circ\): i) \(\phi_0 = 0\) and ii) \(\phi_5 = -\phi_4\). Furthermore, for any given isospin state and \(\theta_{cm}\), there is a hierarchy in helicity amplitudes in the hard regime of the scattering (see e.g. [21,20]):

\[
|\phi_1| \geq |\phi_3|, |\phi_4| > |\phi_0| > |\phi_2|.
\]

(15)

Based on the above features one can do following rather general observations for polarization observables of Eq. (13):

- \(P_y\) and \(C_{x'}\) should be small at large \(\theta_{cm}\), due to the fact that on-shell \(\phi_5\) approaches zero at \(\theta_{cm} \rightarrow 90^\circ\).

Thus the smallness of \(P_y\) and \(C_{x'}\) at \(90^\circ\) will not necessarily indicate an onset of helicity conserving regime in the scattering amplitude. This observation can be checked by looking at \(\theta_{cm}\) dependence of \(P_y\) and \(C_{x'}\). Their increase with \(\theta_{cm}\) going away from \(90^\circ\) will confirm the present conjecture\(^5\).

- Using relations of Eq. (15), from Eq. (13) one can conclude that the relative sign of \(P_y\) and \(C_{x'}\) is related predominantly to the relative phase of \(\phi_5\) and \(\phi_1\). For example, if real and imaginary parts of both \(\phi_5\) and \(\phi_1\) have same signs then \(P_y\) and \(C_{x'}\) will have an opposite signs.

- Based on Eq. (15) on expects \(C_{x'}\) to have a positive values \(\approx 0.5 - 1\).

- The relative sign of \(\phi_3\) and \(\phi_4\) defines the sign of \(\Sigma\). If isovector channel is dominant in the hard \(pn\) rescattering then one expects \(\Sigma > 0\) at \(\theta_{cm} = 90^\circ\).

C. Numerical Estimates

We discuss the numerical estimates for illustration purposes only. Since there are practically no available data on helicity \(pn\) amplitudes for hard scattering kinematics, we model them based on quark-interchange framework of the scattering and the fact that HRM predicts the dominance of isovector state \(NN\) rescattering at \(\theta_{cm} = 90^\circ\). These two features are reflected in the following parameterization (see e.g. [17,18,21]):

\[
\phi_1 = \phi_1 (0) \left[ \frac{17}{62} (F(z_t) + F(z_u)) + \frac{14}{62} (F(-z_t) + F(-z_u)) \right]
\]

\[
\phi_3 = \phi_3 (0) \left[ \frac{25}{94} (F(z_t) + F(z_u)) + \frac{22}{94} (F(-z_t) + F(-z_u)) \right]
\]

\[
\phi_4 = \phi_4 (0) \left[ \frac{1}{4} (F(z_t) + F(z_u)) + \frac{1}{4} (F(-z_t) + F(-z_u)) \right],
\]

(16)

where \(\phi_i (0) \equiv \phi_i^P (\theta_{cm} = 90^\circ)\), \((i = 1, 2, 3, 4)\) and the angular function is defined according to Ref. [21]: \(F(z) = 1/[(1 + z)(1 - z)]^3\), with \(z_t = 1 + \frac{2}{2 - 4 m^2}\), and \(z_u = -1 - \frac{2}{2 - 4 m^2}\). We define \(\phi_2\) as:

\[
\phi_2 = \frac{\phi_2 (0)}{\phi_1 (0)} \phi_1.
\]

(17)

Because of (15) the observables of Eq. (13) depend weakly on the particular choice of \(\phi_2\). To asses the values of \(\phi_{1,2,3,4}(0)\) we use the phenomenological parameterizations of [20], which successfully describe the available polarization and cross section data on hard \(pp\) scattering:

\[\text{Footnote 1:}\]

\footnote{This hierarchy is well founded phenomenologically, even with observed finite effects of helicity nonconservation (see e.g. [20]).}

\[\text{Footnote 2:}\]

\footnote{Inclusion of the \(d\) wave in the deuteron wave function will not change the result, since the additional terms associated with the \(d\) wave are proportional to \(\phi_5\) too.}
\[ \phi_1(0) = \frac{\phi_+ + \phi_-}{\sqrt{2}}; \quad \phi_2(0) = \frac{\phi_+ - \phi_-}{\sqrt{2}}; \quad \phi_4(0) = -\phi_3(0) \]

\[ \phi_{\pm,3}(0) = \frac{N}{(s/GeV^2)^{3/2}} (B_{\pm,3} + C_{\pm,3}e^{i(\Phi_{\pm,3}(s) + \delta_{\pm,3})}) \]  

where \( \phi_{\pm,3} = e^{i(n(s)/A_\Lambda^2)} \) with \( \Lambda \equiv \Lambda_{QCD} \) and all remaining parameters: \( B_i, C_i, a, \Lambda_i \) are defined in Ref. [20] (see Table I).

For \( \phi_5 \) we use relation that ensures a vanishing value at \( \theta_{cm} = 90 \) in the on-shell limit [21]

\[ \phi_5 = R_5^\prime \phi_1 + R_5^\prime (\phi_3 + \phi_4), \]  

where \( R_{5\pm} \) is an angular factor defined similar to [21]:

\[ R_{5\pm}(\hat{t}, \hat{u}) = \epsilon \left[ \frac{1}{\sqrt{-t}} \pm \frac{1}{\sqrt{-u}} \right]. \]

We consider two values for \( \epsilon: \epsilon = \sqrt{\frac{s-4m^2}{2}} \) corresponding to the assumption that the smallness of \( \phi_5 \) at large angles is related only to the condition: \( \phi_5(\theta_{cm} = 90^\circ) = 0 \), and \( \epsilon \approx 0.1 \) – characteristic value obtained from the analysis of \( \phi_5 \) for \( pp \) scattering which takes into account an additional suppression due to helicity conservation [21]. Note that because of the overall smallness of \( \phi_5 \) at large \( \theta_{cm} \) the unpolarized cross section is practically insensitive to the particular choice of \( \epsilon \).

In the hard regime when helicities are conserved \( \phi_5 \) vanishes and its nonzero value is related mainly to the soft component of NN scattering (see e.g. Ref. [19]). Therefore the fact that one can identify the kernel of hard rescattering in Eq.(5) with the hard kernel of NN scattering does not justify the replacement of \( \hat{t} \) and \( \hat{u} \) in \( R_{5\pm} \) by \( t_n \) and \( u_n \). Furthermore, we will refer such a replacement as an “on shell” approximation for \( \phi_5 \). Additionally, we consider an “off-shell” approximations which in the first case (“off-shell I”) we identify \( \hat{t} = -\frac{s-4m^2}{2}(1 - z_t) \) and \( \hat{u} = -\frac{s-4m^2}{2}(1 + z_t) \) and in the second case (“off-shell II”) \( \hat{t} = -\frac{s-4m^2}{2}(1 + z_u) \) and \( \hat{u} = -\frac{s-4m^2}{2}(1 - z_u) \). Note that these are only choices which satisfies the condition, \( |\hat{t}| < |\hat{u}| \) at \( \theta_{cm} < 90 \) (forward angles). The above ambiguity naturally disappears in the on-shell limit.

Fig. 2 demonstrates the HRM predictions for energy dependences of \( P_y, C_\gamma, C_\gamma' \) and \( \Sigma \) at \( \theta_{cm} = 90^\circ \). Thick and thin curves represent the calculations with parameter \( \epsilon \) in Eq.(20) chosen \( \sqrt{\frac{s-4m^2}{2}} \) and 0.1, respectively. Solid and dashed curves correspond to the “on-shell” and “off-shell” approximation for \( \phi_5 \). Note that at \( \theta_{cm} = 90^\circ \) both off-shell approximations give an identical results. According to Eq.(13) the “on-shell” approximation predicts \( P_y \) and \( C_\gamma' \) to be exactly zero at \( \theta_{cm} = 90^\circ \). Thus vanishing \( P_y \) and \( C_\gamma' \) do not indicate unambiguously the onset of helicity conservation regime. The existing data do not rule out the large values for helicity flip amplitudes (thick curves). It is interesting to note that within HRM the small value of \( C_\gamma' \) favors a nonvanishing contribution from \( \phi_2 \) and \( \phi_5 \). Thus the accurate measurement of \( C_\gamma' \) will have an utmost importance.

**IV. SUMMARY**

Polarization observables in \( \gamma D \rightarrow pn \) have been studied within the hard rescattering mechanism of deuteron photodisintegration. Within this model \( P_y, C_\gamma, C_\gamma' \) and \( \Sigma \) asymmetries are expressed through the helicity amplitudes of hard \( pn \) scattering. At \( \theta_{cM} = 90^\circ \) HRM predicts a dominance of the isovector channel in the hard \( pn \) reinteraction.
explained rather by the vanishing
conserving regime. Within HRM this smallness can be
important to have an accurate measurement of
$C_\gamma$ the vanishing helicity non-conserving amplitudes within
scattering at $\theta = 90^\circ$

The definition of the curves are the same as in Fig. 2.

Based on the general constraints on $NN$ helicity amplitudes we predict several qualitative features of $P_y$, $C_{z^\prime}$, $C_x^\prime$ and $\Sigma$. These are the vanishing values of $P_y$, $C_{z^\prime}$ at $\theta_{cm} = 90^\circ$ due to $\phi_5 = 1 (\theta = 90^\circ)$, positive large value for $C_{z^\prime}$ if helicity conserving regime is established, as well as a positive sign for $\Sigma$.

Within the quark-interchange framework we model the $pn$ helicity amplitudes expressing unknown parameters through the existing parameterization of $pp$ amplitudes. Our numerical predictions are in reasonable agreement with the existing data, indicating that the available data are not sufficient to relate unambiguously the observed smallness of $P_y$, $C_{z^\prime}$ to the onset of the helicity-conserving regime. Within HRM this smallness can be explained rather by the vanishing $\phi_5$ amplitude for $NN$ scattering at $90^\circ$ in isovector channel. On the other hand the vanishing helicity non-conserving amplitudes within HRM predict a sizable asymmetry for $C_{z^\prime}$. Thus it is very important to have an accurate measurement of $C_{z^\prime}$. In addition, the study of the angular dependences of $P_y$, $C_{z^\prime}$ and $C_x^\prime$ will clarify unambiguously the question whether the smallness of $P_y$, $C_{z^\prime}$ is related to the vanishing $\phi_5$ at $\theta_{cm} = 90^\circ$ or the onset of helicity conserving regime of high energy scattering. The experimental verification of the sign of $\Sigma$ will check HRM observation that $\theta_{cm} = 90^\circ$ scattering is dominated by hard $pn$ rescattering in the isovector channel.

I would like to thank Drs. S. Brodsky, L. Frankfurt, G. Miller, A. Radyushkin and M. Strikman for many illuminating discussions. I am grateful to Dr. R. Gilman for many useful discussions as well as for providing and explaining the experimental data on $P_y$, $C_{z^\prime}$ and $C_x^\prime$. Special thanks to Dr. A. Sirunyan for providing Yerevan data on $\Sigma$. I thank Jefferson Lab for partial support and Institute for Nuclear Theory at the University of Washington for hospitality during the completion of this work. This work is supported by U.S. Department of Energy grant under contract DE-FG02-01ER41172.

---

FIG. 3. The prediction of $\theta_{cm}$ dependence of $P_y$, $C_{z^\prime}$, $C_x^\prime$ and $\Sigma$ at $E_{\gamma} = 4$ GeV photodisintegration of the deuteron. The definition of the curves are the same as in Fig. 2.
