(Dated: October 13, 2020)

Several independent cosmological data, collected within the last twenty years, revealed the accelerated expansion rate of the Universe, usually assumed to be driven by the so called dark energy, which, according to recent estimates, provides now about 70% of the total amount of matter-energy in the Universe. The nature of dark energy is yet unknown. Several models of dark energy have been proposed: a non zero cosmological constant, a potential energy of some self interacting scalar field, effects related to the non homogeneous distribution of matter, or effects due to alternative theories of gravity. Recently, it turned out that the standard flat ΛCDM is disfavored (at 4 σ) when confronted with a high redshift Hubble diagram, consisting of supernovae of type Ia (SNIa), quasars (QSOs) and gamma ray-bursts (GRBs) ([1–3]). Here we use the same data to investigate if this tension is confirmed, using a different approach: actually in [1–3], the deviation between the best fit model and the ΛCDM model was noticed by comparing cosmological parameters derived from cosmographic expansions of their theoretical predictions and observed high redshift Hubble diagram. In this paper we use a substantially different approach, based on a specific parametrization of the redshift dependent equation of state (EOS) of dark energy component w(z). Our statistical analysis is aimed to estimate the parameters characterizing the dark energy EOS: our results indicate (at > 3σ level) an evolving dark energy EOS, while the cosmological constant Λ has a constant EOS, wΛ = −1. This result not only confirms the tension previously detected, but shows that it is not an artifact of cosmographic expansions.

I. INTRODUCTION

Recent observations of supernovae of type Ia (SNIa) indicate that the expansion rate of the Universe is accelerating [4–9]. This unexpected result was confirmed by analysis of small-scale anisotropies in temperature of the cosmic microwave background radiation (CMBR) [10], and other cosmological data. The observed acceleration is due to so called dark energy, that, in a fluid dynamics approach can be represented by a medium with a negative EOS, \( w = -\frac{1}{3} \). According to observational estimates, dark energy provides now about 70% of matter energy in the Universe.

However the nature of dark energy is unknown. A large variety of models of dark energy have been introduced, including a cosmological constant [11], or scalar field (see for instance [12, 13]).

The accelerated expansion of the Universe could be also expression of the inhomogeneous distribution of matter (see for instance [14]), or effects due to alternative theories of gravity. Therefore the cause of the accelerated expansion of the Universe remains one of the most important open question in Cosmology and Physics: any new, independent measurement related to the expansion rate of the cosmological background, specially in different ranges of redshift, may shed new light on this topic and provide nontrivial test of the standard cosmological model (see [15, 16]).

Indeed, recently, other cosmological probes have entered the game: the first ones are Ghirlanda et al. (2004), Fermiano et al. (2005) using long GRBs ([17], and [18]); Eisenstein et al. (2005) using the imprints of the BAOs in the large-scale structure ([19]); Chavez (2016) using HII galaxies ([20]); Negrete et al. (2017) using extreme quasars [21].

Recently Risaliti & Lusso [1, 2] have shown that the combination of supernovae and quasars can extend and further constrain cosmological models. In [3], some of us found a tension between theoretical predictions of the ΛCDM model and a high-redshift Hubble diagram, on the basis of cosmographic expansions of the observable quantities. Actually, cosmography allows to investigate the kinematic features of the evolution of the universe, assuming only that the space time geometry is described by the Friedman-Lemaître-Robertson-Walker metric, and adopting Taylor expansions, in the traditional approach, or logarithmic polynomial expansions, in a generalized approach [1, 2], of basic cosmological observables.
From observational data it is possible to constrain the cosmographic parameters, and their probability distributions. These constraints can provide information about the nature of dark energy [43], and are model independent, but depend on the properties of convergence of the cosmographic series.

Here we approach this tension from a different point of view, and try to figure out from the observations whether the dark energy equation of state (EOS) evolve or not. Actually it turns out that the cosmological constant $\Lambda$ has a constant EOS, $w_{\Lambda} = -1$, whereas in most cosmological models, following a fluid dynamics approach, we can introduce at least an effective EOS of dark energy, depending on the redshift $z$.

This happens, for instance, in extended theories of gravity [22–25], or in an interacting quintessence cosmology [26]: actually in the generalized Friedman equations, that drive the dynamics of these models, we can identify effective density and pressure terms, and define effective EOS. Understanding from the data whether or not the dark energy EOS is constant, independently of any assumptions on its nature, is, therefore, a daunting yet rewarding task of probing the evolution of dark energy [27].

Here we parameterize $w(z)$ using the Chevallier-Polarski-Linder (CPL) model [28, 29]. Noteworthy in this regard is that we do not intend to use the CPL model to test its robustness in providing reliable reconstruction of dark energy models, as for instance in [30, 31], but, rather, infer from high redshift data if the dark energy EOS is constant or not, and, therefore, if the expansion rate is compatible with the flat $\Lambda$CDM model.

Actually, despite the $\Lambda$CDM enormous success, some tensions and problem have been detected: a combined analysis of the Planck angular power spectra with different luminosity distance measurements are in strong disagreement with the flat $\Lambda$CDM ([32]). Moreover, it turns out that there are some tensions among the values of cosmological parameters inferred from independent datasets. The most famous and persisting one is related to the value of the Hubble constant $H_0$ as measured by Planck and recently by [54] with respect the value extracted from Cepheid-calibrated local distance ladder measurements (see for instance [33]) (the so called $H_0$ tension).

Some papers present interesting attempt to solve this tension. For instance, Poulin et al. ([34]) propose an early dark energy model to resolve the Hubble tension. They assume existence of a scalar field that adds dark energy equal to about 10% of the energy density at the end of the radiation-dominated era at $z \approx 3500$, and then it dilutes; after that the energy density components are the same as in the $\Lambda$CDM model. Another example is the consequence of string theory that predicts existence of an axiverse, i.e. a huge number of extremely light particles with very peculiar physical properties. It seems that a simple modification of the physical properties of these particles is enough to accommodate the Hubble tension ([35]).

In our analysis we use the (SNIa) Hubble diagram (Union2.1 compilation), the gamma-ray burst (GRBs) and QSOs Hubble diagram. We also use Gaussian priors on the distance from the Baryon Acoustic Oscillations (BAO), and the Hubble constant $h$, these priors have been included in order to help break the degeneracies among model parameters. To constrain cosmological parameters we perform Monte Carlo Markov Chain (MCMC) simulations. The structure of the paper is as follows. In Sect. 2 we describe the CPL parametrization used in our analysis. In Sect. 3 we describe the data sets, and in Sect. 4 we describe the statistical analysis and present our results. General discussion of our results and conclusions are presented in Sect. 5.

II. PARAMETRIZATION OF THE DARK ENERGY EOS

Available now observational data imply that the expansion rate of the Universe is accelerating. This accelerated expansion is conveniently described by the standard $\Lambda$CDM cosmological model. However to test if the accelerated expansion is due to the non zero cosmological constant it is necessary to consider a more general model of evolving dark energy that can be described by a simple equation of state (EOS)

$$p_{de}(z) = w(z)\rho_{de}(z),$$  (1)

where $\rho_{de}$ is the effective energy density of dark energy and $p_{de}(z)$ is its pressure. The proportionality coefficient $w(z)$ determines the dark energy EOS. When $w(z) = -1$ the cosmological constant plays the role of dark energy.

In the standard spatially flat Friedman-Lemaitre-Robertson-Walker model the scale factor $a(t)$ is determined by the Friedman equations:

$$H^2 = \left(\frac{\dot{a}}{a}\right)^2 = \frac{8\pi G}{3}(\rho_m + \rho_{de}),$$  (2)

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}(\rho_m + \rho_{de} + 3p_{de}),$$  (3)

where $H$ is the Hubble parameter, the dot denotes the derivative with respect to the cosmic time $t$, and $\rho_m$ is the density of non relativistic matter. When the Universe is filled in with other non interacting matter components their energy density $\rho_i$ and
pressure \( p_i \) are related by EOS for each component of the cosmological fluid \( p_i = w_i \rho_i \) and \( i = 1, \ldots, n \). Non relativistic matter is usually considered to be pressure less so it is characterized by \( w = 0 \). The cosmological constant can be treated as a medium with \( w = -1 \). The non interacting matter components satisfy the continuity equation

\[
\frac{\dot{\rho}_i}{\rho_i} = -3H \left( 1 + \frac{p_i}{\rho_i} \right) = -3H \left[ 1 + w_i(t) \right].
\]  

In the later stages of evolution of the Universe its dynamics is determined only by two components: the non relativistic matter and dark energy. In this case the Friedman equation (2) can be rewritten as

\[
H(z, \theta) = H_0 \sqrt{\Omega_m(z+1)^3 + (1-\Omega_m)g(z, \theta)},
\]

where \( \Omega_m = \frac{8\pi G \rho_m}{3H_0^2} \) is the matter density parameter, and \( g(z, \theta) = \frac{\rho_{de}(z)}{\rho_{de}(0)} = \exp \left( 3 \int_0^z \frac{w(\eta, \theta) + 1}{x+1} \, dx \right) \). Here \( w(z, \theta) \) characterizes the dark energy EOS and \( \theta = (\theta_1, \ldots, \theta_n) \) are additional parameters that describe different models of dark energy. Using the Hubble parameter (5) we define the luminosity distance in the standard way as

\[
d_L(z, \theta) = \frac{c}{H_0} (1+z) \int_0^z \frac{d\zeta}{H(\zeta, \theta)}. \tag{6}
\]

Moreover we can define the angular diameter distance and the volume distance as:

\[
d_A(z, \theta) = \frac{c}{H_0} \frac{1}{1+z} \int_0^z \frac{d\zeta}{H(\zeta, \theta)}, \tag{7}
\]

\[
d_V(z, \theta) = \left[ (1+z) d_A(z, \theta)^2 \frac{cz}{H(z, \theta)} \right]^{\frac{1}{3}}. \tag{8}
\]

To compare predictions of different models of dark energy with high redshift Hubble diagram we use the standard definition of the distance modulus:

\[
\mu(z, \theta) = 25 + 5 \log d_L(z, \theta). \tag{9}
\]

Several different models of dark energy were proposed so far. Here to simplify our analysis we use a two parametric EOS proposed by Chevalier, Polarski and Linder (CPL)

\[
w(z) = w_0 + w_1 \frac{z}{1+z}, \tag{10}
\]

where \( w_0 \) and \( w_1 \) are constants to be determined by the fitting procedure. From the assumed form of \( w(z) \) it is clear that

\[
\lim_{z \to 0} w(z) = w_0, \tag{11}
\]

\[
\lim_{z \to \infty} w(z) = w_0 + w_1. \tag{12}
\]

To check if properties of dark energy change in time it is necessary to use high redshift data to find out if \( w_1 \) is zero or not.

### III. THE DATA SETS

To perform our analysis and determine the basic cosmological parameters, we construct a Hubble diagram by combining four data samples. In our analysis we build up a Hubble diagram spanning a wide redshift range. To this aim we combine different data sets.
Figure 1: Hubble diagram of SNIa (red points), quasars (gray points) and GRBs (green points), with their respective 1σ uncertainties.

A. Supernovae Ia

SNIa observations gave the first strong indication of the recent accelerating expansion of the Universe ([5] and [6]). In our analysis we use the recently updated Supernovae Cosmology Project Union 2.1 compilation [36], containing 580 SNIa, spanning the redshift range (0.015 ≤ z ≤ 1.4). We compare the theoretical distance modulus $\mu(z)$, based on the definition of the distance modulus in different cosmological models:

$$\mu(z_j) = 5 \log_{10}(D_L(z_j; \theta_i)) + \mu_0,$$

(13)

where $D_L(z_j; \theta_i)$ is the Hubble free luminosity distance, and $\theta_i$ indicates the set of parameters that appear in different dark energy equations of state considered in our analysis. The parameter $\mu_0$ encodes the Hubble constant and the absolute magnitude $M$. We used an alternative version of the $\chi^2$:

$$\tilde{\chi}^2_{SN}([\theta_i]) = c_1 - \frac{c_2}{c_3},$$

(14)

where

$$c_1 = \sum_{j=1}^{N_{SNIa}} \frac{(\mu(z_j; \mu_0 = 0, \{\theta_i\}) - \mu_{obs}(z_j))^2}{\sigma_{\mu,j}},$$

(15)

$$c_2 = \sum_{j=1}^{N_{SNIa}} \frac{(\mu(z_j; \mu_0 = 0, \{\theta_i\}) - \mu_{obs}(z_j))^2}{\sigma_{\mu,j}},$$
\[
    c_3 = \sum_{j=1}^{N_{SN_{Ia}}} \frac{1}{\sigma_{\mu,j}}.
\]

It is worth noting that
\[
    \chi^2_{SN}(\mu_0, \{\theta_i\}) = c_1 - 2c_2\mu_0 + c_3\mu_0^2,
\]
which clearly has a minimum for \( \mu_0 = \frac{c_2}{c_3} \), so that
\[
    \hat{\chi}^2_{SN} \equiv \chi^2_{SN}(\mu_0 = \frac{c_2}{c_3} \{\theta_i\}) .
\]

B. Gamma-ray burst Hubble diagram

Gamma-ray bursts are visible up to high redshifts thanks to the enormous released energy, and therefore are good candidates for our high-redshift cosmological investigations. They show non thermal spectra which can be empirically modeled with the Band function, i.e., a smoothly broken power law with parameters: the low-energy spectral index \( \alpha \), the high energy spectral index \( \beta \) and the roll-over energy \( E_0 \). Their spectra show a peak corresponding to a specific (and observable) value of the photon energy \( E_p = E_0(2 + \alpha) \); indeed it turns out that for GRBs with measured spectrum and redshift it is possible to evaluate the intrinsic peak energy, \( E_{p,i} = E_p(1 + z) \) and the isotropic equivalent radiated energy
\[
    E_{iso} = 4\pi d_L(z, \theta) (1 + z)^{-1} \int_{1/(1+z)}^{10^{\beta/(1+z)}} EN(E)dE ,
\]
where \( N(E) \) is the Band function:
\[
    N(E) = \begin{cases} 
    A \left( \frac{E}{100keV} \right)^\alpha \exp \left( \frac{-E}{E_0} \right), & (\alpha - \beta) \geq 0, \\
    A \left( \frac{(\alpha-\beta)E}{100keV} \right)^{\alpha-\beta} \exp (\alpha - \beta) \left( \frac{E}{100keV} \right)^\beta, & (\alpha - \beta) E_0 \leq E , 
    \end{cases}
\]
\( E_{p,i} \) and \( E_{iso} \) span several orders of magnitude (GRBs cannot be considered standard candles), and show distributions approximated by Gaussians plus a tail at low energies. However in 2002, based on a small sample of BeppoSAX, it turned out that \( E_{p,i} \) is strongly correlated with \( E_{iso} \) [38]. This correlation, commonly called Amati relation within the GRB community, has been confirmed in subsequent observations and provide a reliable instrument to standardize GRBs as a distance indicator, in a way similar to the Phillips relation to standardize SNIa (see, for instance, [37],[43, 44] and reference therein). It is clear from Eq. (18) that, in order to get the isotropic equivalent radiated energy, \( E_{iso} \) it is necessary to specify the fiducial cosmological model and its basic parameters. But we want to use the observed properties of GRBs to derive the cosmological parameters. Several procedures to overcome this circular situation have been proposed (see for instance [39–42]).

Here we performed our analysis using a GRB Hubble diagram data set obtained by calibrating the \( E_{p,i} - E_{iso} \) correlation on a SNIa data ([43, 44]). Actually we applied a local regression technique to estimate the distance modulus \( \mu(z) \) from the SCP Union2 compilation. To obtain an estimation of \( \mu(z) \) we order the SNIa dataset according to increasing values of \( |z - z_i| \). Therefore we select the first \( n = \alpha N_{SN_{Ia}} \), where \( \alpha \) is a user selected value and \( N_{SN_{Ia}} \) the total number of SNIa. Then we fit a first order polynomial to these data, weighting each SNIa with the corresponding value of an appropriate weight function, like, for instance
\[
    W(u) = \begin{cases} 
    (1 - |u|^2)^2 & |u| \leq 1 \\
    0 & |u| \geq 1 .
    \end{cases}
\]

The zeroth order term is the best estimate of \( \mu(z) \). The error on \( \mu(z) \) is provided by the root mean square of the weighted residuals with respect to the best fit value. In Eq. (19) \( u = |z - z_i|/\Delta \) and \( \Delta \) indicates the maximum value of the \( |z - z_i| \) over the chosen subset. Having estimated the distance modulus at redshift \( z \) in a model independent way, we can fit the \( E_{p,i} - E_{iso} \) correlation using the local regression reconstructed \( \mu(z) \) in Eq. (18). It is worth noting that we already discussed some aspects of this topic in our previous papers [42],[44], where, apart from other issues, we described how it is possible to simultaneously constrain the calibration parameters and the set of cosmological parameters: we found that the calibration parameters are fully consistent with the results obtained from the SNIa calibrated data.
In order to investigate a possible $z$ dependence of the correlation coefficients, in the calibration procedure we added terms representing the $z$-evolution, which are assumed to be power-law functions: $g_{iso}(z) = (1 + z)^{k_{iso}}$ and $g_p(z) = (1 + z)^{k_p}$ ([44]). Therefore $E_{iso}' = \frac{E_{iso}}{g_{iso}(z)}$ and $E_{p,i}' = \frac{E_{p,i}}{g_p(z)}$ are the de-evolved quantities included in a 3D correlation:

$$\log \left( \frac{E_{iso}}{1 \text{ erg}} \right) = b + a \log \left( \frac{E_{p,i}}{300 \text{ keV}} \right) + (k_{iso} - a k_p) \log (1 + z).$$

This de-evolved correlation was calibrated applying the same local regression technique previously adopted ([43, 44]), but considering a 3D Reichart likelihood:

$$L^{3D}_{Reichart}(a, k_{iso}, k_p, b, \sigma_{int}) = \frac{1}{2} \sum \log \left( \frac{\sigma^2_{int} + \sigma^2_{y_i} + a^2 \sigma^2_{x_i}}{\sigma^2_{y_i} + \sigma^2_{x_i} + a^2 \sigma^2_{x_i}} \right) + \frac{1}{2} \sum \frac{(y_i - ax_i - (k_{iso} - \beta) z_i - b)^2}{\sigma^2_{int} + \sigma^2_{y_i} + a^2 \sigma^2_{x_i}},$$

(21)

where $\beta = a k_p$. We also used the MCMC method to maximize the likelihood and ran five parallel chains and the Gelman-Rubin convergence test. We found that $a = 1.87^{+0.08}_{-0.09}$, $k_{iso} = -0.04 \pm 0.1$; $\beta = 0.02 \pm 0.2$; $\sigma_{int} = 0.35^{+0.02}_{-0.03}$, so that $b = 52.8^{+0.03}_{-0.06}$. After fitting the correlation and estimating its parameters, we used them to construct the GRB Hubble diagram. Detailed discussion of the GRBs sample and possible selection effects is presented also in ([37, 44, 46]).

C. Quasars

A physical relation has been observed between the optical-UV disk and the X-ray corona consisting in a log-log relation between their respective fluxes. From previous studies, Lusso et al. (see [1]) found out a dispersion varying between 0.35 to 0.4 dex in this correlation. Their first sample was further reduced by eliminating quasars with host galaxy contamination, reddening, X-ray obscured objects and radio loudness (Lusso & Risaliti, 2016) to reach a dispersion of 0.21-0.24 dex. The quasar sample used here is presented in [2, 3] and consists of 1598 sources in the redshift range $0.04 < z < 5.1$. Distance moduli have been estimated by calibrating the power-law correlation between the ultraviolet and the X-ray emission observed in quasars [1–3]). More details on the sample are provided in [3].

D. H(z) data

The Hubble parameter depends on the differential age of the Universe and can be measured using the cosmic chronometers: usually, $dz$ is obtained from spectroscopic surveys, and, if cosmic chronometers are identified, we can measure $dt$, in the redshift interval $dz$. We used a list of 28 $H(z)$ measurements, compiled in [50]. The Hubble parameter $H(z)$ can be measured through the differential age technique, based on passively evolving red galaxies as cosmic chronometers. Actually it turns out that $H(z)$ depends on the differential variation of the cosmic time with redshift according to the following relation:

$$H(z) = -\frac{1}{1 + z} \left( \frac{dt}{dz} \right)^{-1}.$$

(22)

The term $\left( \frac{dt}{dz} \right)$, is estimated from the age of old stellar populations in red galaxies from their high resolution spectra.

E. BAOs

In order to reduce the degeneracy among cosmological parameters we also use some constraints from standard rulers. Actually the BAOs, which are related to imprints of the primordial acoustic waves on the galaxy power spectrum, are widely used as such
rulers. In order to use BAOs as constraints, we follow [51] by first defining:

\[ d_z = \frac{r_s(z_d)}{d_V(z)} , \]  

(23)

with \( z_d \) being the drag redshift, \( d_V(z) \) the volume distance, and \( r_s(z) \) the comoving sound horizon given by:

\[ r_s(z) = \frac{c}{\sqrt{3}} \int_0^{(1+z)^{-1}} \frac{da}{a^2 H(a) \sqrt{1 + (3/4) \Omega_b/\Omega_\gamma}} , \]

(24)

here \( \Omega_\gamma \) is the radiation density parameter. We fix \( r_s(z_d) = 152.6 \) Mpc and the volume distance is defined in Eq. (8). The values of \( d_z \) at \( z = 0.20 \) and \( z = 0.35 \) have been estimated by Percival et al. (2010) using the SDSS DR7 galaxy sample ([51]) so that we define \( \chi^2_{BAO} = D^T C_{BAO} D \) with \( D = (d_{0.2}^{obs} - d_{0.2}^{th}, d_{0.35}^{obs} - d_{0.35}^{th}) \) and \( C_{BAO} \) is the BAO covariance matrix.

IV. STATISTICAL ANALYSIS

To compare the high-redshift data described above with the CPL parametrization, we use a Bayesian approach, and we apply the MCMC method to maximize the likelihood function \( \mathcal{L}(p) \):

\[ \mathcal{L}(p) \propto \exp(-\chi^2_{GRB}/2) \left( \frac{\sigma_{GRB}}{2\pi} \right)^{-N/2} |C_{GRB}|^{-1/2} \exp(-\chi^2_{QSO}/2) \left( \frac{\sigma_{QSO}}{2\pi} \right)^{-N/2} |C_{QSO}|^{-1/2} \times \exp(-\chi^2_{SNIa}/2) \left( \frac{\sigma_{SNIa}}{2\pi} \right)^{-N/2} |C_{SNIa}|^{-1/2} \exp(-\chi^2_{BAO}/2) \left( \frac{\sigma_{BAO}}{2\pi} \right)^{-N/2} |C_{BAO}|^{-1/2} \times \exp(-\chi^2_{BAO}/2) \left( \frac{\sigma_{BAO}}{2\pi} \right)^{-N/2} |C_{H}|^{-1/2} . \]

(25)

In the Eq. (25)

\[ \chi^2(p) = \sum_{i,j=1}^{N} (x_i - x_i^{th}(p)) C_{ij}^{-1} (x_j - x_j^{th}(p)) , \]

(26)

where \( p \) denotes the parameters that determine the cosmological model, \( N \) is the number of data point. \( C_{ij} \) is the covariance matrix ( \( C_{SNIa/GRB/QSO/H} \) indicates the SNIa/GRBs/QSO/H covariance matrix). The term \( \exp(-\chi^2_{H}/2) \left( \frac{\sigma_{H}}{2\pi} \right)^{-N/2} |C_{H}|^{-1/2} \) in Eq. (25) is the likelihood relative to \( H(z) \). It is worth noting that by joining the GRB and QSO Hubble diagrams we can probe the background cosmological expansion over a redshift range more appropriate for studying dark energy than the one covered by SNIa only. We used a Metropolis-Hastings algorithm: we start from an initial parameter vector \( \theta^{start} \), and we generate a new trial vector \( \theta^{next} \) from a tested density \( f(\theta^{next}, \theta^{start}) \), which represents the conditional probability of \( \theta^{next} \), given \( \theta^{start} \). The probability of accepting the new vector \( \theta^{next} \) is described by

\[ F(\theta^{next}, \theta^{start}) = \min \left\{ 1, \frac{\mathcal{L}(\theta^{next}) Pr(\theta^{next}) f(\theta^{next}, \theta^{start})}{\mathcal{L}(\theta^{start}) Pr(\theta^{start}) f(\theta^{start}, \theta^{start})} \right\} \]

(27)

where \( d \) are the data, \( \mathcal{L}(d|p) \propto \exp(-\chi^2/2) \) is the likelihood function, \( Pr(\theta) \) is the prior on the parameters. Moreover we assume that \( f(\theta^{start}, \theta^{next}) \propto \exp(-\Delta \theta^2/2\delta^2) \), with \( \Delta \theta = (\theta^{start} - \theta^{next}) \), and the dispersion \( \delta = 15\% \) for any step.

In order to sample the space of parameters, we use a Metropolis-Hastings test to control the convergence of the chains. We use uniform priors for the parameters. After that we conservatively discard the first 30\% of the point iterations at the beginning of any MCMC run, and thin the chains, we finally extract the constraints on cosmological parameters by co-adding the thinned chains. Histograms of the parameters from the merged chains were used to estimate the median values and confidence ranges. In Tables (I), (II) we report results of our analysis. It is worth noting that \( \sigma_{int} \) is the observed dispersion of the QSO Hubble diagram, and it is of order of 0.2 dex. If we compare this value with dispersion in the Hubble diagram of SNIa, which is \( \sigma_{SN} \sim 0.07 \) at \( z \sim 1 \), it turns out that QSOs provide the same cosmological information as SNIa. For the GRBs Hubble diagram we do not provide the observed dispersion here, because it has been evaluated during the calibration of the \( E_p - E_{iso} \) correlation and used to estimates the error bars in the GRB Hubble diagram. In Figs. (2), (3), and (4) we show 2D confidence regions: it turns out that the dark energy EOS does evolve with redshift, and the ACDM model, i.e. \( w_0 = -1 \) and
Table I: Constraints on the CPL parameters from different data: combined SNIa, GRBs, and QSOs Hubble diagrams, $H(z)$ data sets, and BAO data. Columns show the mean $\langle x \rangle$ and median $\tilde{x}$ values and the 68% and 95% confidence limits.

$w_1 = 0$ is disfavored (at more than $3\sigma$) with all the data, thus showing the importance of independent and complementary data sets, specially in different ranges of redshift. Actually our results, not based on cosmographic expansions, confirm the tension between predictions of the $\Lambda$CDM model and observations found previously in [1–3]. In order to highlight that this result is due to the contribution of the high redshift QSO and GRB Hubble diagram we first used these sample only: the results are shown in Table (II) (right panel). In Figs. (5) and (6) we plot the distribution of the residuals as a function of redshift for the GRB and QSO samples. It turns out that the amplitude of the scatter of the residuals show no significant trend with redshift. Moreover the deviation from the $\Lambda$CDM model emerges at high redshifts: it turns out that if we select GRBs and QSOs at $z \leq 1$, the corresponding Hubble diagram is well reproduced by the standard flat $\Lambda$CDM, as shown in Table (III). Similarly when we fit the GRB and QSO Hubble diagram fixing $\Omega_m = 0.31$, as we show in Table (IV), we found that the $\Lambda$CDM with $\Omega_m = 0.31$ reproduces the data at $1\sigma$. Finally it is worth noting that future missions, like, the THESEUS observatory [52] for GRBs, and eRosita all sky survey for QSOs ([53]) will substantially increase the number of data usable to construct the Hubble diagram at high redshift and so help to probe the nature of dark energy. Actually the main power of the GRB and QSO Hubble diagram for cosmological investigations lies in the high-redshift regime, where it is possible to discriminate among different cosmological models and also different theories of gravity.

V. CONCLUSIONS

The nature of the dark energy and the origin of the accelerated expansion of the Universe remain one of the most challenging open questions in Physics and Cosmology. The flat $\Lambda$CDM model is the most popular cosmological model used by the scientific community. However, despite its enormous successes, some problems have been detected: quite recently it turned out that there is a tension (at more than $3\sigma$) between cosmological and local measurements of the Hubble constant ([33]). Moreover, recently in [1–3, 45], another tension has been also reported between predictions of the $\Lambda$CDM model and the Hubble Diagram of SNIa and quasars. With the aim of clarifying this result, we concentrated on the possibility to detect, from different and independent data, evidence of a redshift evolution of the dark energy equation of state: we performed statistical analysis to constrain the dark energy EOS, using the simple CPL parametrization. Our high redshift Hubble diagram provides a clear indication (at $3\sigma$ level) of an evolving dark energy EOS, thus confirming the previous results [45], and highlight the importance, to explore the cosmological expansion, of using independent probes and exploring large ranges of redshift. It turns out that the deviation from the standard $\Lambda$CDM is due just to the QSO and GRBs Hubble diagrams. Moreover it is important for $z > 1$: if, indeed we limit our analysis to $z \leq 1$ the $\Lambda$CDM reproduces the data at $1\sigma$. The residuals do not present any significant trend systematic with

---

1 It is worth noting that the values of the QSOs and GRBs distance module are not absolute, thus cross calibration parameters are needed (for both GRBs and QSOs data). Therefore the Hubble constant $H_0$ is degenerate with these calibration parameters, and it cannot be constrained.
Table II: Constraints on the CPL parameters from different data: combined SNIa and GRB Hubble diagrams, and $H(z)$ data sets (Left Panel); QSO and GRB Hubble diagram (Right Panel). Columns show the mean $\langle x \rangle$ and median $\tilde{x}$ values and the 68% and 95% confidence limits.

Figure 2: 2D confidence regions in the $w_0 - w_1$ plane for the CPL model, obtained from all the data sets. It turns out that the case $w_0 = -1, w_1 = 0$, corresponding to the standard $\Lambda$CDM model, is disfavored at 3σ, in full agreement with the results of [3] that use a different approach. The red and black points correspond to the best fit value and the mean respectively.

redshift: this evidence further proves that our results are not affected by systematics.
Figure 3: 2D confidence regions in the $w_0 - w_1$ plane for the CPL model, obtained from SNIa, GRB Hubble diagram and the $H(z)$ measurements. It turns out that the case $w_0 = -1, w_1 = 0$, corresponding to the $Λ$CDM model, is disfavored at more than $3σ$. The red point corresponds to the best fit value and the mean respectively, that in this case are indistinguishable.

With future missions, like, the THESEUS observatory, and the eRosita all-sky survey, that will substantially increase the number of GRBs and QSOs usable to construct the Hubble diagram it will be possible to better test the nature of dark energy.
