Abstract We investigated some properties of coronal mass ejections (CMEs), such as speed, acceleration, polar angle, angular width and mass, using data acquired by LASCO aboard of SOHO from July 31, 1997, to March 31, 2014, i.e., during the solar cycles 23 and 24. We used two CME catalogs: one provided by the CDAW Data Center and one obtained by the CACTus detection algorithm. For both dataset, we found that the number of CMEs observed during the peak of cycle 24 was higher or comparable to the one during cycle 23, although the photospheric activity during cycle 24 was weaker than during cycle 23. More precisely, using the CMEs detected by CACTus we noted that the number of events $N$ is of the same order of magnitude during the peaks of the two cycles, but the peak of CME distribution during the cycle 24 is more extended in time ($N > 1500$ during 2012 and 2013). We ascribe the discrepancy between CDAW and CACTus results to the observer bias for CME definition in the CDAW catalog (Robbrecht \textit{et al.}, 2009; Webb and Howard, 2012; Yashiro \textit{et al.}, 2008). We also used a dataset containing 19811 flares of C, M, and X class, observed by GOES during the same period. Using both dataset, we studied the relationship between the mass ejected by the CMEs and the flux emitted during the corresponding flares: we found 11441 flares that were temporally-correlated with CMEs for CDAW and 9120 for CACTus. Moreover, we found a log–linear relationship between the flux of the flares integrated from the start to end in the 0.1–0.8 nm range and the CME mass: $\log(\text{CME mass}) \propto 0.23 \times \log(\text{flare flux})$. We also found some differences in the mean CMEs velocity and acceleration between the events associated with flares and those that were not. In particular, the CMEs associated with flares are on average $\sim 100$ km/s faster than the ones not associated with flares.

Keywords: Coronal Mass Ejections, Iniziation and Propagation; Flares, Dynamics.
1. Introduction

Many studies of eruptive phenomena occurring in the solar atmosphere, such as flares, filament eruptions and coronal mass ejections (CMEs) are aimed at understanding the role that the global and local magnetic fields play in their triggering. According to most recent theoretical and observational works, flares, filaments, and CMEs are all manifestation of the same physical phenomenon: magnetic reconnection. However, the temporal and spatial relationships among these events are still unclear. A preliminary aspect in this kind of investigation concerns the properties of CMEs.

For instance, Ivanov and Obridko (2001) studied the semiannual mean CME velocities for the time interval 1979-1989 and revealed a complex cyclic variation with a peak at the solar cycle maximum and a secondary peak at the minimum of the cycle. The growth of the mean CME velocity is accompanied by a growth of the mean CME width. Moreover, they concluded that the secondary peak of the semiannual mean CME velocity in 1985-1986 is due to a significant contribution of fast CMEs with a width of about $100^\circ$ at the minimum of the cycle. This peak is supposed to be due to the increasing role of the global large-scale magnetic field system at the minimum of the solar cycle.

Chen et al. (2011), reexamined whether flare-associated CMEs and filament eruption-associated CMEs have distinct velocity distributions and investigated which factors may affect the CME velocities. They divided the CME events observed from 2001-2003 into three types, i.e., the flare-associated type, the filament eruption associated type, and the intermediate type. For the filament eruption associated CMEs, the speeds were found to be strongly correlated with the average magnetic field in the filament channel.

Cremades and Cyr (2007) presented a survey of events observed during the period 1980-2005 and found that the latitude of CME matches well with the location of coronal streamers in agreement with Hundhausen (1993).

More recently, Mittal et al. (2009a) have analyzed more than 12900 CMEs observed by SOHO/LASCO during the period 1996-2007. They found that the speeds decrease in the decay phase of the solar cycle 23. There is an unusual drop in speed in the year 2001 and an abnormal increase in speed in the year 2003. This increase corresponded with the so named Halloween events, i.e., the high concentration of CMEs, X-class flares, solar energetic particle (SEP) events and interplanetary shocks observed during the months of October and November of that year. The same dataset showed that about 66% of CMEs have negative acceleration, 25% have positive acceleration and the remaining 9% have very low acceleration (Mittal and Narain (2009b)) in the outer corona.

Some difficulties in understanding the relationships between flares and CMEs are due to the different methods of observation that must be used to investigate these phenomena. In fact, the coronagraphs, used to observe the outer corona where the CMEs are detected, occult the solar disk and do not allow one to observe the source region where the corresponding flares take place. Therefore, many authors tried to study these relationships from a statistical point of view.

For example, St. Cyr and Webb (1991) considered a dataset of 2 years, i.e., from 1984 to 1986 acquired by the Solar Maximum Mission (SMM), (Phillips
Correlation between flares and CMEs over the solar cycle 23 and 24

Table 1. Previous results on the correlation between CMEs, flares and eruptive prominences

| Authors                        | Number of events | Period       | CMEs of eruptive prominences | CMEs Hα flares | CMEs X-ray flares |
|--------------------------------|------------------|--------------|-------------------------------|----------------|------------------|
| St. Cyr and Webb (1991)        | 73 CMEs          | 1984-1986    | 76%                           | 26%            | 74%              |
| Gilbert et al. (2000)          | 18 CMEs          | 1996-1998    | 76%                           | 94%            |                  |
| Subramanian and Dere (2001)    | 32 CMEs          | 1996-1998    | 76%                           | 94%            |                  |
| Zhou, Wang and Cao (2003)      | 197 CMEs         | 1997-2001    | 94%                           | 88%            |                  |

(1990) (see Table 1), found that 76% of the CMEs were associated with erupting prominences, 26% with Hα flares, and 74% with flares observed in the X-ray range. Gilbert et al. (2000), analyzing 18 CMEs observed by the Large Angle Spectrometric Coronograph (LASCO) C2 (Brueckner et al., 1995) and the Ground based Mark-III K-Coronometer (MK3) at the Mauna Loa Solar Observatory (MLSO) (MacQueen and Fisher, 1983; St. Cyr et al., 1999) and 54 flares observed in Hα during 2 years of observation, between 1996 and 1998, found that 94% of Hα flares were associated to CMEs and that 76% of the CMEs were associated with eruptive prominences. Moreover, analyzing the same period, Subramanian and Dere (2001) using LASCO and EUV Imaging Telescope (EIT) instrument aboard of the Solar Heliospheric Observatory (SOHO, Delaboudinière et al. 1995) found that 44% of the CMEs were associated with eruptions of prominences embedded in an active region, while 15% with eruptions occurred outside active regions.

Zhou, Wang and Cao (2003) used data taken by LASCO aboard of SOHO from 1997 to 2001 and selected 197 front-side halo CMEs. They found that 88% of those CMEs were associated with flares, while 94% were associated with eruptive filaments. For 59% of the CMEs, their initiation seemed to precede the associated flare onset recorded by the Geostationary Operational Environmental Satellite (GOES, Howard, 1974; Ludwig and Johnson, 1981) while 41% CMEs seemed to follow the flare onset.

Many authors (see for example Gopalswamy et al. 2013; Youssef 2012) investigated also possible relationships between the CMEs physical parameters and the flare properties not excluding the narrow CMEs and using only CDAW dataset, even though the CaCTus catalog was developed around 2004. The authors point out that the list is necessarily incomplete because of the nature of identification. In the absence of a perfect automatic CME detector program, the manual identification is still the best way to identify CMEs (Youssef 2012).

Using the LASCO and EIT data taken by the SOHO satellite, Zhang et al. (2001a) analyzed four events and found that the impulsive acceleration phase of the selected CMEs coincided well with the rise phase of the associated X-ray flares. Later, Qiu and Yurchyshyn (2005) studied 11 events with varying magnetic field configurations in the source regions and concluded that the CMEs velocities were proportional to the total magnetic reconnection flux, while their kinetic energy was probably independent of the magnetic configuration of the source regions.
A very deep analysis on the correlation between X-ray flares and CMEs using GOES and LASCO archives from 1996 to 2006 has been performed by Aarnio et al. (2011). They considered 13682 CMEs and selected 826 flare-CME pairs. They found that the CME mass increases with the flare flux, following an approximately log-linear relationship: \( \log(\text{CME mass}) \propto 0.70 \log(\text{flare flux}) \). while the CME mass appears unrelated to its acceleration. Aarnio et al. (2011) also noted that CMEs associated with flares have higher average linear speeds (495\(\pm\)8 km/s) and negative average acceleration (1.8\(\pm\)0.1 m/s\(^2\)), while CMEs not associated with flares have lower average linear speed (422\(\pm\)3 km/s) and positive average acceleration (0.07 \(\pm\) 0.25 m/s\(^2\)). Finally, the width of CMEs resulted to be directly correlated with the flare flux: X class flares are associated with the widest CMEs (80\(^\circ\) \(\pm\) 10\(^\circ\)), while B class flares are associated with the narrowest CMEs (42\(^\circ\) \(\pm\) 1.4\(^\circ\)).

In this context, we intend to provide a further contribution to the knowledge of CMEs properties and of the correlation between flares and CMEs. In this paper we present the results obtained from the analysis of a dataset more extended than the one of Aarnio et al. (2011), including 22876 CMEs and 19811 flares of C, M and X-GOES class observed from July 31, 1996, to March 31, 2014. We investigate how some previous mentioned relationships vary with the solar cycle. In the next section we describe our dataset, in section 3 we show our results and in section 4 we deal with the discussion of the results and draw our conclusions.

2. Data description

The CMEs data used in this work were acquired by LASCO C2 and C3 coronagraphs aboard of SOHO during about 17 years (from July 31, 1997, to March 31, 2014). We used the CDAW Data Center online CME catalogue, which is available at the following link:

http://cdaw.gsfc.nasa.gov/CME_list/ and the catalog obtained by the Computer Aided CME Tracking software (CACTus), which is available at the following link: http://sidc.oma.be/cactus/. The use of both catalogs allowed us to compare the results from manual identification of CMEs (CDAW) and automatic tracking of CMEs (CACTus).

The CDAW catalogue contains information on several CMEs parameters, such as their central Polar Angle (PA), i.e. the mean angle between the two outer edges of the CME width measured counterclockwise from Solar North in degrees on the plane of the sky, the linear velocity, the acceleration, the width, the mass, and the energy. The CACTus catalog contains all information of CDAW catalogue except the mass, the energy and the acceleration of the events. We remark that the CME start time reported in these catalogs corresponds to the first detection of the CME in the LASCO C2 field of view, i.e the region from 2.0 to 6.0 solar radii. The whole CDAW dataset contains 22876 events, while CACTus contains 15515 events.

We also considered 19811 flares of C, M and X class occurred during the same time interval and observed by GOES. We used the reports of the National Geophysical Data Center (NGDC) (ftp://ftp.ngdc.noaa.gov/) to collect the main
3. Results

3.1. CME parameters over the solar cycles

In order to show the occurrence distribution of CMEs during the solar activity cycle, we report in Fig. 1 the number of CMEs (N) observed by LASCO during each year of our observation time interval (the black and the dot-dashed blue lines correspond to the data obtained from the CDAW and CACTus catalogs, respectively.) We clearly see two peaks corresponding with the maxima of the solar cycles 23 and 24. In particular, we note that for the CDAW dataset the peak of the cycle 24 is higher than the one referring to cycle 23. This result seems to be in contrast with the fact that the magnetic activity during the cycle 24 was weaker than during the cycle 23 (Tripathy et al. (2015)), as shown in Fig. 1 (red line), where the yearly Wolf number is reported. Moreover, using the CMEs detected by CACTus we note that N is of the same order of magnitude during the peaks of the two cycles, and that the peak of CME distribution during the cycle 24 is more extended in time (N > 1500 during 2012 and 2013). The different results obtained from CDAW and CACTus could be ascribed to the observer bias for CME definition in the CDAW catalog (Robbrecht et al., 2009; Webb and Howard, 2012; Yashiro et al., 2008). Moreover as far as the higher or comparable number of CMEs recorded during cycle 24, despite the low number of sunspots observed during this cycle, it is worth of note to recall that Gopalswamy et al. (2015) found a similar result from the analysis of halo CMEs.

In Fig. 2 (from top to bottom) we show the behavior of the average annual velocity, acceleration and angular width for all the observed CMEs during the solar cycles 23 and 24. For the velocity and the angular width we plot the results of CDAW dataset (black line) and of CACTus dataset (dot-dashed blue line), while for the acceleration we show only the CDAW results because this parameter is not available in the CACTus dataset.

We calculate the CME annual mean velocity by considering the total number of CMEs for each year and then considering the velocity averaged with respect to this number. The same procedure was applied for the other parameters. We also computed the error bars for the mean distribution of these quantities, as \( \sigma/\sqrt{N} \), where \( \sigma \) is the standard deviation of the corresponding quantity and \( N \) is the number of CMEs occurred in each year. The error bars are smaller than the symbol sizes, although the error for the acceleration is dominated by the uncertainty of the individual measurements. The red line in each panel shows the yearly Wolf number. For the average velocity we can see a first peak around 2003 and a second one between 2012 and 2014 in both datasets. The behavior of
Figure 1. Number of CMEs per year observed by LASCO during the selected time interval. The black and dot-dashed blue lines indicate the results for the CDAW and CACTus catalogs, respectively. The red line indicates the yearly Wolf Number during the same period.

both datasets reflects the solar activity cycles and can be interpreted according to Qiu and Yurchyshyn (2005) as an effect of the magnetic flux involved by the events during the solar maxima. However, one difference between the two datasets is that in the mean velocity distribution of the CMEs detected by CACTus there is another peak between 2008 and 2010, during the minimum of the solar cycle. A secondary peak was reported by Ivanov and Obridko (2001) from the analysis of CMEs velocities for the time interval 1979-1989, and was interpreted by these authors as due to a significant contribution of fast CMEs ($V > 400\text{km/s}$) with a width of 100$^\circ$.

The mean CMEs acceleration for CDAW is $3.17 \pm 0.3\text{m/s}^2$. In the distribution of the CME average acceleration (middle panel of Fig. 2) we see negative values around the maximum of the solar cycle 23 and a peculiar peak of about $15 \pm 2.7\text{m/s}^2$ in 2009. We note that this peak occurs approximately when we observe the minimum in the annual average velocity distribution for CDAW and the second peak of the velocity distribution for CACTus. However, we argue that statistically the slower CMEs are characterized by higher positive values of acceleration.

In Fig. 2 (bottom panel), showing the mean angular width, the values in the years 2000-2003 for CDAW dataset ($\approx 20^\circ$) suggest that on average the narrowest CMEs are the slowest ones (compare with Fig. 2 (top panel)) (Yashiro et al.,
Figure 2. Distribution of the mean annual CMEs velocity (top panel), acceleration (middle panel) and angular width (bottom panel) from 1996 to 2014. The black and dot-dashed blue lines indicate the results for the CDAW and CACTus catalogs, respectively. In each panel the yearly Wolf number is reported (red line).
Figure 3. Distribution of the velocity of the CMEs in each year between 2000 and 2006 for CDAW (red line) and CACTus catalogs (blue line).

We note also that for the CACTus dataset the fastest CMEs are the narrowest (Yashiro et al. (2008)). Both datasets show a minimum in the mean width distribution over the years corresponding to the minimum of the solar cycle, although Yashiro et al. (2008) found that the CACTus catalog has a larger number of narrow CMEs than CDAW. This difference in the two samples determines a different amplitude in the range spanned by the mean angular width distribution, i.e. for CACTus catalog the mean width varies from $\sim 30^\circ$ during the minimum of solar activity to $\sim 40^\circ$ during the maximum of activity, while for CDAW catalog varies between $\sim 20^\circ$ and $\sim 80^\circ$.

In order to further analyze the properties of CMEs during the descending part of the solar cycle 23 (from 2000 to 2006), in Fig. 3 and 4 we show the distribution of the velocity, acceleration and width of the CMEs.

In Fig. 3 we can see that the tail of the distribution of the velocity decreases when going from the maximum (2000) to the minimum (2006) of the cycle. This means that most of the fastest CMEs velocities ($> 1000\ km/s$) occur during the maximum of the solar cycle, when the amount of magnetic field emerged in the atmosphere reaches higher values. The average velocity of the CMEs for CDAW during these years is $396.25 \pm 1.67\ km/s$, where this uncertainty error is the standard deviation of the mean, while the mean velocity for CACTus is $491.78 \pm 2.66\ km/s$. We also remark that in Fig 3 we can see few CMEs characterized by velocities $\geq 600\ km/s$ (note that in these plots the velocities are not averaged on each year as in Fig. 2 (top panel)).
Correlation between flares and CMEs over the solar cycle 23 and 24

Figure 4. Distribution of the acceleration of the CMEs in each year between 2000 and 2006.

Figure 5. Distribution of the CMEs angular width in each year between 2000 and 2006 for CDAW (red line) and CACTus (blue line). The latter bin refers to halo CMEs.
Figure 6. Distribution of the polar angle (PA) along which the CMEs propagate in each year between 2000 and 2006 for CDAW (red line) and CACTus (blue line). The PA is measured in degrees from the Solar North in counter-clockwise direction.

The CME accelerations in each year (Fig. 4) are distributed mainly between -50 m/s$^2$ and 50 m/s$^2$, and few events are characterized by higher values during the maximum of the solar cycle. We note an increase of the difference between the negative and the positive accelerations while the solar activity decreases. Therefore, the average acceleration per year is mainly negative during the years of higher activity and is positive during the minimum of the solar cycle, as already shown in Fig. 2 (middle panel).

The angular width distribution (see Fig. 5) shows that the majority of the CMEs are characterized by an angular width lower than 100°. We note that the CACTus dataset presents a greater number of CMEs narrower than 40° and a smaller number of CMEs wider than 40° in comparison with the CDAW dataset (see Yashiro et al. (2008)). The mean angular sizes (latitudinal extents) projected against the plane of the sky of all CMEs of the CDAW dataset is 55°.78 ± 0°.44, i.e., slightly greater than 50° as found by Cane (2000). The mean CMEs width for CACTus dataset is 39°.48 ± 0°.38. Only during the maximum of the solar cycle (2000 and 2001) we observe a significant number of CMEs with a width larger than 100°. The last bin of the plots in Fig. 5 represents the halo CMEs contained in the CDAW catalog, i.e CMEs with angular width of 360°. Our dataset, composed by 22876 CMEs, contains 616 halo CMEs, i.e 2.69% of total CMEs.

We used the same sample of years to study the variation in time of the distribution of the Polar Angle (PA) along which the CME propagated (Fig. 6).
For both datasets we can see two peaks centered around the PA corresponding to low latitudes, i.e. where the ARs form and where the CMEs start. We note that the distribution of PA changes in time from a broader distribution in 2000 (near the maximum of the solar cycle 23) to a more peaked distribution in 2006 (near the minimum of the solar activity). We deduce that the latitude distribution of CMEs follows the latitude distribution of the closed magnetic field regions in the corona, which is consistent with the fact that the CMEs originate in closed field regions (Hundhausen, 1993).

3.2. Flare distribution over the solar cycles

Using the dataset relevant to flares of C, M and X class observed by GOES, during the period 1996-2014, we determine the total number of flares per year. The result is reported in Fig. 7 (black line), where we can see two peaks approximately corresponding to the maxima of the solar activity cycles. The maximum of the solar cycle 23 is quite long: in 2000, 2001 and 2003 we observed about 2500 flares per year. We see also that the maximum of flare activity in 2014 corresponds to the peak of the Wolf Number in the cycle 24. In 2008 we observed only 11 flares: 10 of C class and 1 of M class.

![Figure 7. Total flares distribution in the selected time interval (black line) and yearly Wolf Number (red line).](image)

When we distinguish among the C, M, and X class flares (Fig. 8) we see that the maxima of the M class flares occurred in 2002 and in 2014 and that both the C and the M class flare distribution have a higher maximum during the cycle 23.
than during the cycle 24 (we recall that a different result was found for CMEs, see Fig. [1]).

3.3. Correlation between flares and CMEs

In order to determine the possible association between one CME and one flare, we used a temporal criterion, requiring that both flare and CME occur within a set time window. We initially set time windows to select CMEs first observation time that occurs within ±2h of the flare start time, peak time, or end time, using both datasets. When we consider the CDAW dataset and the flare start time, we find that the highest number of CMEs and flares (59.57% ) is characterized by a difference in time between 10 and 80 min (see the black line in the top panel of Fig. [9], confirming the results obtained by Aarnio et al. [2011]. The distribution of the CME-flare associated events for the CACTus dataset (bottom panel of Fig. [9] is slightly different from the CDAW dataset. In fact, we observe a wider time range (from -30 to 110 min) for the occurrence of most of the associated events. Considering the flare start time and a time interval of ±2h, we found 11441 and 9120 flares associated with CMEs using the CDAW and the CACTus catalogs, respectively. The distributions of these flares according to the GOES class are reported in Table [2]. In both cases the temporal shift between

| GOES class | Number of events | flare associated with CME ±2h (Percentage) | CMEs not associated with flares (Percentage) | flare associated with CME ±2h (Percentage) | CMEs not associated with flare (Percentage) |
| C     | 17712 | 10003 (56.47%) | 11074 (48.40%) | 7755 (43.78%) | 6396 (41.22%) |
| M     | 1884  | 1308 (69.43%)  | 1242 (65.92%)  | 121 (78.06%)  |
| X     | 155   | 130 (89.39%)   | 121 (78.06%)   |
| Halo CMEs | 616 | 315 (51.14%)  | 301 (48.86%)  |

Table 3. Results on the correlation between CMEs and flares for CDAW and CACTus datasets in the ±1h time interval.

| Flares | CDAW | CACTus |
|--------|------|--------|
| GOES class | Number of events | flare associated with CME ±1h (Percentage) | flare associated with CME ±1h (Percentage) |
| C     | 17712 | 5842 (32.98%) | 4228 (23.87%) |
| X     | 155   | 118 (76.13%)  | 86 (55.48%)   |
| M     | 1884  | 951 (50.48%)  | 771 (40.92%)  |

the flare and the CME decreases if we consider the distributions obtained using the flare peak time and the flare end time (see Fig. 9). In Table 2, 3, and 4, we report the associated CMEs-flares using only a temporal criteria. In this way we obtained in first approximation a high number of CMEs associated with flares, that drastically decreases when we apply a spatial correlation between these events to select the true-associated events as described in Sect. 4, so that finally we found only 1277 CMEs associated with flares that are spatially and temporally correlated.

The same analysis was performed using the time intervals ±1h and ±30min and the flare start time. The results are reported in Tables 3 and 4. Similar behavior of the correlation between CMEs and flares in different time intervals and in different GOES classes has been found for both datasets. We ascribe the smaller number of CACTus CMEs associated with X-class flares to the limits of the CACTus algorithm in the detection of the fastest CMEs Yashiro et al. (2008).

The distributions of C, M, and X class flares associated with CMEs, as a function of the years in the solar cycle in the time interval of ±2h, ±1h, ±30min, are shown in Figs. 10 and 11 for CDAW and CACTus, respectively. We note
Figure 9. Distribution of the CME-flare associated events as a function of the time difference between the CME first observation and the flare start (black), peak (red), and end time (green). CT and FT refer to CME first observation time and flare time, respectively. The top and bottom panels refer to the CDAW and CACTus datasets, respectively.
Table 4. Results on the correlation between CMEs and flares for CDAW and CACTus datasets in the ±30min time interval.

| Flares | CDAW | CACTus |
|--------|------|--------|
|        | flare with CME ±30min (Percentage) | flare with CME ±30min (Percentage) |
| GOES   | Number of events |                  |                          |
| C      | 17712 | 2992 (16.89%) | 2159 (12.19%) |
| M      | 1884  | 445 (23.62%)  | 341 (18.099%) |

that the probability to find CMEs associated with flares decreases when the time window is narrower. However, we see that the peak and the shape of the distributions remain similar, independent of the considered time window. In the top panel of Figs. 10 and 11 the peaks correspond to the years 2000-2002 and 2011-2014, in agreement with the solar activity cycles (see Fig. 1). We can see in the distribution of C class flares associated with CMEs (top panels of Figs. 10 and 11) that these events are present also during the phases of minimum of solar activity. In the distribution of M class flares, (middle panels of Figs. 10 and 11) we can see a trend very similar to the one found for C-class flares. On the other hand, we note that the distribution of X class flares associated with CMEs is more uniform across the solar cycle than the one of C and M class flares for both datasets. For example, for CDAW in 1998 and 2005 we observe 14 and 18 X class flares associated with CMEs respectively, while for CACTus we observe 6 and 8 X class flares in those years, although the phase of the solar cycle and the magnetic activity was not high. However, when we consider only the flares associated with CMEs in ±30min time window, we find a distribution of the X class flares more consistent with the solar cycle for both distributions.

In Fig. 12 we show the distribution of CMEs velocity, distinguishing between events associated with flares in the ±2h time window and events not associated with flares. The mean CMEs velocities in CDAW datasets for the CMEs associated and not associated with flares are 472.87 ±2.77 km/s and 379.41 ±2.25 km/s, respectively. The mean CMEs velocities in CACTus dataset for the CMEs associated and not associated with flares are 500.62 ±3.28 km/s and 437.75 ±3.79 km/s respectively. In Fig. 12 (right panel) we note that there are a great number of CMEs not associated with flares in the CACTus dataset with velocities between 100-200 km/s.

The distribution of the CME acceleration (left panel of Fig. 13) shows that the CMEs associated with flares have an average acceleration of -0.32 ± 0.34 m/s², while the CMEs not associated with flares have an average acceleration of 3.44 ± 0.39 m/s². In the right panel of Fig. 13 we report the distribution of the CMEs mass. The logarithm of mean CME mass for CMEs associated with flares and not are 14.70 ± 0.006 g and 14.54 ± 0.004 g, respectively.
Figure 10. Total distribution of C class (top panel), M class (middle panel), X class (bottom panel) flares associated with the CMEs as a function of years in ±2h time window (blue), in ±1h time window (red) and ±30min time window (green) for CDAW. The black line in each panel indicates the distribution of all flares for a given class.
Figure 11. Total distribution of C class (top panel), M class (middle panel), X class (bottom panel) flares associated with the CMEs as a function of years in ±2h time window (blue), in ±1h time window (red) and ±30min time window (green) for CACTus. The black line in each panel indicates the distribution of all flares for a given class.
Further we found different linear velocity distributions when we distinguish among the three flare classes (Fig. 14). The CDAW velocity distribution of the CMEs associated with the C class flares shows a significant peak at 250 km/s which is not present in the CACTus velocity distribution. For CDAW the mean linear velocities of CMEs associated with flares of C, M, and X classes are $535.95 \pm 1.11 \text{km/s}$, $585.71 \pm 8.16 \text{km/s}$ and $626.99 \pm 56.58 \text{km/s}$, respectively. For CACTus the mean velocities of CMEs associated with flares of C, M, and X classes are $487.91 \pm 3.46 \text{km/s}$, $562.16 \pm 9.82 \text{km/s}$ and $688.15 \pm 34.35 \text{km/s}$,
Correlation between flares and CMEs over the solar cycle 23 and 24 respectively. Both distributions are similar except that the number of events in CACTus is smaller than CDAW, as we note in the distribution of CMEs associated with C class flares (see the blue line in Fig. [14]). It is worth noting the differences between the velocity of CMEs associated with X class flares in the CDAW dataset and in the CACTus dataset. In fact the CMEs associated with flares in the CACTus dataset are faster than the ones of the CDAW dataset.

In Fig. [15] we show the relationship between CME speed and acceleration, taking into account the different class of the associated flares. We found that the majority of CMEs characterized by higher velocities are associated with acceleration between $-200$ and $200 \text{ m/s}$

On the other hand, there are many CMEs with a wide range of acceleration (between $-400$ and $400 \text{ m/s}^2$) but with velocity below $700 \text{ km/s}$. These CMEs are mainly associated with C and M class flares.

4. CME parameters and flare energy

We used our dataset to investigate the relationship between the logarithm of the flare flux and the logarithm of the CME mass. In this case we considered not only the temporal correlation between flares and CMEs, but also their spatial correlation. We limited this analysis to flares which occurred in the time window of $\pm 2h$ and characterized by a known location of the source region over the solar disc. We associated flares which occurred in the top left quadrant of the solar disc with CMEs characterized by a polar angle between $0^\circ$ and $89^\circ$, flares occurred in the bottom left quadrant with CMEs characterized by a polar angle between $90^\circ$ and $179^\circ$, etc. This criterion of association between flares and CMEs is based on the assumption that most CMEs propagate nearly radially, according to the standard CME–flare model (see Lin and Forbes (2000)). We obtained in this way 1277 CMEs that are spatially and temporally correlated with flares. We considered the flux of these flares integrated from their start to end in the $0.1$–$0.8 \text{ nm}$ range. Subsequently the 1277 flare/CME pairs have been binned into 13 equal sets of 100 pairs each, with the exception of the last one containing 77 pairs. We computed the mean value of the logarithm of the CME mass and the logarithm of flare flux in each group. The relationship between the logarithm of the CME mass and the logarithm of the flare flux is shown in Fig. [15] where we also show the error bars of the logarithm of the CMEs mass computed as $\sigma/\sqrt{N}$. The flux error bars corresponds to the minimum/maximum flare flux values spanned by that bin. The results shown in Fig. [15] are similar to the result reported by Aarnio et al. (2011). In fact we found the following log–linear relationship between integrated flare flux and CME mass:

$$\log(\text{CME mass}) = (15.33 \pm 0.10) + (0.23 \pm 0.04) \times \log(\text{flare flux}).$$ (1)

However, it worth noting that this relationship disappears when we limit the same analysis to each year of our dataset (we do not show the corresponding plots in this paper). This means that the log–linear relationship between integrated flare flux and CME mass is consistent only for a large huge sample of events, but it is not valid during the different phases of the solar cycle.
The $\chi^2$ test of the linear fit that we have performed is 0.07. Further tests to verify the goodness of the fit have also been performed. The Spearman’s coefficient, indicating how well the relationship between two variables can be described using a monotonic function, is 0.82 which indicates a good correlation between these quantities. We also found a p-vale of 0.85 and a linear Pearson correlation coefficient of 0.87.

5. Conclusions

In this paper we used the huge dataset of the CMEs observed for nearly all of the operational time of the LASCO mission onboard of SOHO to infer some properties of these events over the solar cycles 23 and 24 and to study their correlation with the flares observed in the X-ray range, between, 1.0 and 8.0 $\AA$, by GOES. We used two CME catalogs; one based on manual identification of CMEs (CDAW) and one based on their automatic tracking (CACTus).

From the analysis that we have performed we conclude that the peak in the number of CMEs in cycle 24 is higher than the one of cycle 23. In particular, for the CDAW dataset the number of CMEs at the maximum of solar cycle 24 is higher than the one at the maximum of solar cycle 23; for CACTus the peaks during the maxima are similar, but the one corresponding to solar cycle 24 is more extended in time than the one corresponding to the solar cycle 23. This result seem to be in contrast with the fact that the magnetic activity during the cycle 24 was weaker than during the cycle 23, as noted in the work of Tripathy et al. (2015) that analyzed the frequency shifts of the acoustic solar modes measurement separately for the two cycles, and found that the magnetic activity during solar cycle 24 was weaker than during cycle 23.

Solar cycle 24 has been extremely weak as measured by the sunspot number (SSN) and is the smallest since the beginning of the Space Age. The weak activity has been thought to be due to the weak polar field strength in cycle 23. Several authors have suggested that the decline in cycle 24 activity might lead to a global minimum. (Padmanabhan et al., 2013; Zolotova et al., 2014). From the analysis of the CME average velocity, we found two peaks that reflect the solar activity cycles and can be interpreted, according to Qiu and Yurchyshyn (2005) as an effect of the magnetic flux involved by the events during the solar maxima, but we also observe another peak at the minimum of the cycles, even if only for the CACTus dataset, in the year 2009. This peak agree with the cyclic variation of the CMEs velocity with the previous solar activity cycles, as reported by Ivanov and Obridko (2001).

From the distribution of the average acceleration of the CMEs, we see a maximum of about $15m/s^2 \pm 2.71m/s^2$, corresponding to the minimum of the distribution of the average velocity (see Fig. 2 upper and middle panel). We think that this peak may be due to the contribution of the slower CMEs occurring during the minimum of the solar activity, which are characterized by higher positive values of acceleration.

We found also that the tail of the distribution of the higher velocities of the CMEs observed during the descending part of solar cycle 23 (from 2000 to 2006)
is no longer present when going from the maximum (2000) to the minimum (2006) of the cycle (see Fig. 3).

The distribution of the CME angular width for CDAW shows that on average, the narrower CMEs are slower and the majority of the CMEs are characterized by an angular width lower than 100°. Only during the maximum of the solar cycle (2000 and 2001) do we observe a significant number of CMEs with an angular width larger than 100° ± 0°.44.

The CDAW and CACTus datasets present a different amplitude of the range spanned by the mean angular width, i.e. for CACTus catalog the mean width varies from ~ 30° during the minimum of solar activity to ~ 40° during the maximum of activity, while for CDAW the mean width varies from ~ 20° to ~ 80°.

The latitude distribution of CMEs follows the latitude distribution of the closed magnetic field regions of the corona, which is consistent with the fact that CMEs originate in closed field regions (Hundhausen, 1993). We also note that the distribution of PA changes in time from a broader distribution in 2000 (near the maximum of the solar cycle 23) to a more peaked distribution in 2006 (near the minimum of the solar activity).

Using the dataset of CMEs and flares and selecting the event occurring in the same time window of ±2h,±1h and ±30min we indentified CMEs and flares temporally correlated.

Despite the number of associated CMEs-flares temporally and spatially correlated might seems low, Aarnio et al. (2011), studying the correlation between flares flux and CMEs mass, found similar result with 826 associated CMEs-flares during the time interval 1996-2006. Youssef (2012), studied the correlation between flare flux and CME energy and found 776 associated CMEs-flares during the time interval 1996-2010. Considering the flare start time, we found that the highest number of CMEs and flares detected in the CDAW dataset (59.57%) are characterized by a difference in time between 10 and 80 min (see the black line in the top panel of Fig. 9), in agreement with Aarnio et al. (2011). The CMEs-flares associated events for the CACTus dataset show a wider temporal range. We argue that this difference between the two datasets depends on the different criteria used by the observer for defining a CME in CDAW. A time window of 10-80 min is clear evidence that in many cases the flare occurs before the first observation of the CME in the coronograph and, taking into account that the time resolution of LASCO is about 30 min.

There are a number of cases in which the flare most likely precedes the CME initiation and may be the first manifestation of the initiation process. One should also need to investigate the role of filaments/prominences in the initiation.

The shape of the distributions of C, M, and X class flares associated with CMEs varies with the intensity of the flares (see Figs. 10 and 11), but it is similar for both datasets. In particular, we note that the distribution of X class flares associated with CMEs is quite uniform with respect to the one of C and M class flares across the solar cycle. However, when we consider only the flares associated with CMEs in the ±30min time window, we find a distribution of the X class flares more consistent with the solar cycle (see Fig. 10 bottom panel).
We found that most of the CMEs characterized by higher linear velocities are associated with flares (see e.g. Gosling et al. (1976); Moon et al. (2003)).

The mean velocities for CMEs associated with flares are higher than the velocities for CMEs not associated with flares in both datasets. Our results are therefore very similar to those found by Aarnio et al. (2011).

Moreover, our analysis shows that the width of the CMEs associated with flares is positively directly correlated with the flare flux. The mean angular width of the flares associated with CMEs is $68^\circ.61$, $116^\circ.82$, $258^\circ.49$ for C, M and X flares, respectively.

The distribution of the CME acceleration (left panel of Fig. 13) shows that the CMEs associated with flares have an average acceleration of $-0.32 \pm 0.34 m/s^2$, while the CMEs not associated with flares have an average positive acceleration of $3.44 \pm 0.37 m/s^2$. We suggest that these values are slightly different from those found by Aarnio et al. (2011) due to the different sample of events considered in our paper.

We also used our dataset to further extend the study on the log–linear relationship between the flare flux and the CME mass performed by Aarnio et al. (2011). In this case, we considered not only the temporal correlation between flares and CMEs, but also their spatial correlation. As mentioned above, this allows us to be more confident that the CMEs and the flares may be linked, although some events may be neglected. We found that $\log(CME \ mass) \propto 0.23 \times \log(flare \ flux)$. The differences between the results of Aarnio et al. (2011) and ours may be due to several reasons. First of all we considered a more extended dataset. We also used the flux of the flares integrated from their start to end in the 0.1–0.8 nm range. Finally, we used different criteria to determine the association between flares and CMEs. Therefore, we conclude that the log–linear relationship is valid not only when we consider the peak of the flare flux, but also when we consider the energy released during the whole event.

It is worth of note that this relationship disappears when we limit the sample of flare/CME pairs to the different phases of the solar cycle. This means that the log–linear relationship is valid only from a statistical point of view, i.e. when we consider a large sample of events.

We argue that this result is due to different aspects (intensity of magnetic field, magnetic reconnection, configuration of sunspot on the solar surface) that influence the evolution of these phenomena. Further study and analysis must be made on the intensity of the magnetic flux involved in these phenomena and consequently on the capacity to eject the mass into the interplanetary space. In fact, the magnetic configuration can play an important role in determining the different ways to buildup and release magnetic free energy and the role of magnetic reconnection.

Acknowledgments. The authors wish to thank the anonymous referee for her/his useful suggestions which allowed to improve the Paper. This research work has received funding from the European Commissions Seventh Framework Programme under the Grant Agreements no. 606862 (F-Chroma project) and no. 312495 (SOLARNET project). This research is also supported by the ITA MIUR-PRIN grant on ”The active sun and its effects on space and Earth climate” and by Space WEather Italian COnmunity (SWICO) Research Program. We are also grateful to the University of Catania for providing the Grant FIR 2014.
Correlation between flares and CMEs over the solar cycle 23 and 24
