(Dated: March 5, 2018)

Large unsaturated magnetoresistance has been recently reported in numerous semi-metals. Many of them have a topologically non-trivial band dispersion, such as Weyl nodes or lines. Here, we show that elemental antimony displays the largest high-field magnetoresistance among all known semi-metals. We present a detailed study of the angle-dependent magnetoresistance and use a semi-classical framework invoking an anisotropic mobility tensor to fit the data. A slight deviation from perfect compensation and a modest variation with magnetic field of the components of the mobility tensor are required to attain perfect fits at arbitrary strength and orientation of magnetic field in the entire temperature window of study. Our results demonstrate that large orbital magnetoresistance is an unavoidable consequence of low carrier concentration and the sub-quadratic magnetoresistance seen in many semi-metals can be attributed to field-dependent mobility, expected whenever the disorder length-scale exceeds the Fermi wavelength.

Detailed studies of magnetoresistance have been carried out in a large variety of systems ranging from ferromagnetic-metallic multilayer devices \cite{1}, manganite perovskites \cite{2}, and doped semi-conductors \cite{3}. The large increase in the resistivity of semi-metals, which appears when the magnetic field is applied perpendicular to the orientation of the electric current has been known for a long time \cite{4}. Recently, such a large orbital magnetoresistance has been observed in many dilute metals. The list includes three-dimensional Dirac systems (Cd$_3$As$_2$ \cite{5}), Weyl semi-metals (WTe$_2$ \cite{6}, NbP \cite{7} or WP$_2$ \cite{8,9}, LaBi \cite{10}), but also ‘trivial’ semi-metals (LaSb \cite{11}, gray arsenic \cite{12}). Reporting on the large magnetoresistance in WTe$_2$, Ali \textit{et al.} \cite{5} contrasted its unsaturated B$^2$ behavior to the quasi-linear and eventually saturating high-field magnetoresistance of well-known semi-metals such as bismuth and graphite. Soon afterwards, WTe$_2$ was identified as a type-II Weyl semimetal \cite{13}. During the last three years, the link between amplitude and the field-dependence of magnetoresistance and its possible link to non-trivial electronic topology became a subject of debate and motivated numerous studies.

Here, we present the case of elemental antimony, another well-known semi-metal. Despite the remarkably high mobility of its bulk carriers \cite{14} and its topologically non-trivial surface states \cite{14}, its large bulk magnetoresistance \cite{15,16} has never been studied in detail. Its carrier density of $n$\textasciitilde$p$\textasciitilde$5.5 \times 10^{19}$ cm$^{-3}$ \cite{18} is comparable to WTe$_2$ ($n$\textasciitilde$p$\textasciitilde$6.6 \times 10^{19}$ cm$^{-3}$ \cite{19}) and two orders of magnitude larger than bismuth ($n$\textasciitilde$p$\textasciitilde$3 \times 10^{17}$ cm$^{-3}$ \cite{20}). We show that in a reasonably clean Sb single crystal, a magnetic field of 56 T enhances resistivity by a factor of $\Delta \rho / \rho_{0} = 3 \times 10^6$. This is one order of magnitude higher than what was reported in WTe$_2$ \cite{6}, and comparable with what was observed in WP$_2$ \cite{8}. The field dependence of magnetoresistance is close to (but slightly different from) quadratic. We present an angle-dependent study, with magnetic field kept perpendicular...
to the applied current and rotating in three perpendicular crystalline planes (as in the case of bismuth [20]), and employ a semiclassical picture, based on distinct mobility tensors for electrons and holes, to explain the data. We show that by assuming slightly imperfect compensation, one can explain the finite Hall response. Taking into account a smooth field-induced reduction in mobility allows perfect fits to the non-quadratic magnetoresistance and the non-linear Hall resistivity at the same time. Thus, antimony becomes the first semi-metal whose extremely large magnetoresistance is totally explained by an extended semiclassical treatment for any arbitrary amplitude and orientation of magnetic field.

The two additional assumptions required to attain perfect fits bring new insight to the apparent diversity of semi-metallic magnetoresistance. Imperfect compensation caused by 1 part per million (ppm) of uncontrolled doping is barely noticeable when there is one hole and one electron per 10^4 atoms, that is when carrier density is in the range of 10^{10} cm^{-3}. But the same amount of uncontrolled doping has a much stronger signature when the carrier density is two orders of magnitude lower. This explains why the high-field magnetoresistance is close to quadratic in Sb and WTe₂, but almost linear in Bi. The field-induced reduction in mobility can be caused by a disorder invisible to long-wavelength electrons at zero-field and becoming relevant in presence of magnetic field. Since the electron wave-function is smoothly squeezed by magnetic field, Raleigh scattering by extended defects becomes more efficient as the Landau levels are depopulated [21]. This provides a simple, but non-universal foundation for the field-induced decrease in mobility leading to the ubiquitous non-quadratic magnetoresistance.

Fig. 1a) presents the reported magnetoresistance of numerous semimetals at B=9T and T=2K (See [22] for details). The amplitude of field-induced enhancement in resistivity is plotted as a function of zero-field mobility, extracted from resistivity and carrier density: \( \mu_0 = \frac{1}{\rho_0 (n + p)} \). Here, \( e \) is the charge of the electron, \( n \) and \( p \) are the electron and hole densities and \( \rho_0 \) the zero-field resistivity at T=2K. One can see that across more than three orders of magnitude, the MR of semi-metals (topological or not) roughly scales with their zero-field mobility. The higher the mobility, the larger the magnetoresistance. However, one can also see that systematically \( \Delta \rho / \rho_0 \) is lower than 81<\( \mu_0^2 \), which is what is expected for 9 T if the mobility was the same unique number relevant to the two (zero-field conductivity, \( \sigma = e(n\mu_e + p\mu_h) \), and finite-field magnetoresistance).

Even the most ideally simple semimetal requires more complexity. Such a system would have a single electron-like and a single hole-like Fermi surface. The two pockets are isotropic with scalar mobilities of \( \mu_e \) and \( \mu_h \). The semi-classic magnetoresistance of such a system would be \( \Delta \rho / \rho_0 = \mu^2 > B^2 \), where \( \mu_p = \sqrt{\mu_e \mu_h} \). Note that the zero-field average mobility is \( \mu_0 = \frac{n\mu_e + p\mu_h}{n + p} \). The two average mobilities are identical only when \( n=p \) and \( \mu_e = \mu_h \). However, \( \mu_0 \) and \( \mu_m \) remain of the same order of magnitude.

As seen in Fig. 1a, despite the discovery of numerous new compounds, the three elemental semimetals (Bi, Sb and As) are still those showing the largest magnetoresistance at 9 T. Fig. 1b) compares the field dependence of magnetoresistance in bismuth, WTe₂ and antimony at T=2K and B≤56 T. One can see that it is close to B² in Sb and WTe₂, but presents a lower exponent (B¹.₅) and a tendency to saturation in bismuth. As a consequence, antimony surpasses bismuth above \( \approx 25 \)T. Note that the amplitude of magnetoresistance in a given metal is not fixed and depends on the cleanness as we will discuss.
The angle-dependence of the magnetoresistance at T=2K and B=12T measured on the same sample for the three perpendicular planes of field rotation are presented in Fig.2d, f, h. In each case, the profile of $\rho_{ii}(\theta)$ reflects the symmetry of the projected profile of the Fermi surface components in that plane (Fig.2e, e, g). When the current is along the binary and the magnetic field rotates in the P1 plane, there is only the inversion symmetry so that $\rho_{11}(\theta)=\rho_{11}(\pi+\theta)$. When the current is along the bisectrix and a magnetic field rotates in the P2 plane, as a consequence of additional mirror symmetry, $\rho_{22}(\theta)=\rho_{22}(-\theta)$. Finally, when the current is along the trigonal and the field rotates in the P3 plane, sixfold oscillations results as a consequence of the C3 symmetry combined with the inversion symmetry. In contrast to bismuth [20] we did not observe any field-induced loss of threefold symmetry (see section E of [22] for more details).

In order to extract the components of the mobility tensor for electrons and holes, we used the formalism developed first by the Mackey and Sybert [24] and then by Aubrey [25]. In this approach, the total conductivity is the sum of the contributions by each valley expressed as:

$$\hat{\sigma}_{e,h} = ne \left( \hat{\rho}^{-1}_{e,h} + \hat{B} \right)^{-1}$$  \hspace{1cm} (1)
ellipsoids for electrons, we could extract the components of the mobility tensor along the three principal axes. By employing this formalism, the Hall response is obtained by considering the evolution of a slight departure from perfect compensation and taking into consideration the evolution of \( e, h, \mu \), and holes, \( \nu_i (i=1, 2, 3) \). Further details can be found in [22] section D.

We needed to add two ingredients to this formalism in order to substantially improve the fits. These were a slight departure from perfect compensation and taking into consideration the evolution of \( e \) and \( h \) with magnetic field. In this formalism, the Hall response is expected to be linear in the high-field regime (\( \mu B \gg 1 \)) if the compensation is perfect. As illustrated in Fig. 3, d), experimentally, this is not the case. The non-linear Hall resistivity can be captured by assuming a slight imbalance between hole and electron density, \( \frac{\Delta n}{n} = \frac{\nu_e - \nu_h}{n} \). We find that the best agreement with data yields \( \frac{\Delta n}{n} = 7 \times 10^{-4} \). This roughly corresponds to one defects per million unit cell, consistent with the 5N quality Sb powder used to grow the sample and with early galvanometric measurements [15].

The consistency of our analysis is checked by comparing the field dependence of \( \rho_{11} \), \( \rho_{22} \) and \( \rho_{33} \) (See Fig. 4a-d). One can see that imperfect compensation combined with a slight field-dependence of the components of the mobility tensor provides a satisfactory description of the overall field dependence of \( \rho_{11} \), \( \rho_{22} \) and \( \rho_{12} \).

Our best simultaneous fits of \( \rho_{11} \), \( \rho_{22} \) and \( \rho_{33} \) at T=2K and B=12T are represented in red in Fig. 4. We performed similar fits at different temperature and magnetic fields (see Fig. 5) to obtain the magnitude of the components of the mobility tensors at any magnetic field and temperature in Fig. 5. One can see that the temperature dependence closely tracks the temperature dependence of the zero-field mobility along the trigonal axis: \( \mu_0(\rho_{33}) = \frac{1}{m^* \rho_{33}(B=0)} \). At low temperature, the compo-

where \( \hat{B} \) is defined as:

\[
\hat{B} = \begin{pmatrix}
0 & -B_3 & B_2 \\
B_3 & 0 & -B_1 \\
-B_3 & B_1 & 0
\end{pmatrix}
\]

Here, \( \mu_{e,h} \) is the mobility of electrons and holes. \( B_1, B_2 \) and \( B_3 \) are the projections of the magnetic field vector along the three principal axes. By employing this formalism, we could extract the components of the mobility tensor along the principal axes of the representative ellipsoids for electrons, \( \mu_e \), and holes, \( \nu_i (i=1, 2, 3) \). Further details can be found in [22] section D.
The field dependence of the components of the mobility tensor is also instructive. When the field is swept from 0.5T to 12T, $\nu_1$, $\nu_2$, $\nu_3$ are almost constant, but $\mu_2$ and $\mu_3$ decrease by a factor of 1.5 and $\mu_3$ by a factor of 3. The fact that magnetic field does not affect in a similar manner among different components of the mobility tensor is a clue to the origin of the scattering process which becomes more effective in presence of magnetic field. The drastic decrease in $\mu_3$ indicates that disorder in the orientation perpendicular to the cleaving planes becomes more significant with increasing field. Another piece of evidence is provided by contrasting samples with different levels of disorder. As presented in [22], the sub-quadratic aspect of magnetoresistance becomes more pronounced in dirtier samples where both the RRR (Residual Resistivity Ratio) and the Dingle mobility, $\mu_D$, are lower. A ratio of $\mu_3$ as large as 300 implies a significant role for small angle scattering. We thus identify long-range disorder as the ultimate source of sub-quadratic magnetoresistance.

In conclusion, we found a very large magnetoresistance in elemental antimony towering over most reported cases. We showed that the magnitude of the magnetoresistance at any temperature and magnitude or orientation of the magnetic field can be explained using a semi-classical framework with two additional ingredients, a weak deviation from perfect compensation and a field-dependent mobility tensor. The same framework can be used to address all other semi-metals. We conclude that because of slight imperfect compensation sub-quadratic magnetoresistance is unavoidable. In antimony or in WTe$_2$, the carrier concentration is large enough to cover the role played by imperfect compensation, yet small enough to allow carriers to have a large mobility. This is the main reason behind its towering magnetoresistance. The phenomenological achievement reported here is only one step towards a microscopic theory. The challenge is to describe the anisotropic effect of magnetic field on carriers with a known dispersion in presence of a precise scattering potential. This would pin down the intrinsic limits of mobility in a given material.
