Purpose: To evaluate the effect of aflibercept treatment after developing ranibizumab tachyphylaxis for the treatment of polypoidal choroidal vasculopathy (PCV).

Patients and methods: Ten eyes from ten patients with PCV who developed ranibizumab tachyphylaxis were reviewed. Tachyphylaxis was defined as when repeated intravitreal ranibizumab (IVR) resulted in a complete lack of response after initial treatment response. All treatments were converted to intravitreal aflibercept (IVA) after development of ranibizumab tachyphylaxis. Central retinal thickness (CRT) was compared at baseline, at complete resolution after IVR, at reactivation after IVR, at initial IVA, and at 4 and 12 weeks after initial IVA.

Results: Mean number of IVR treatments before conversion to IVA was 11.3 (range 5–16). All eyes had positive therapeutic responses after conversion to IVA. Mean CRT at 4 and 12 weeks after initial IVA was significantly decreased from baseline initial IVA (P = 0.005).

Conclusion: Switching therapy to aflibercept is effective for patients with PCV who develop tachyphylaxis to ranibizumab.

Keywords: polypoidal choroidal vasculopathy, ranibizumab, aflibercept, tachyphylaxis

Introduction

Polypoidal choroidal vasculopathy (PCV), which was first described by Yannuzzi et al, is characterized by numerous recurrent, bilateral, asymmetric, serosanguinous detachments in the retinal pigment epithelium. Several treatment strategies have been reported for PCV. Among them, photodynamic therapy and intravitreal injection of anti-vascular endothelial growth factor (VEGF) including ranibizumab (Lucentis; Genentech, San Francisco, CA, USA) have shown favorable results. However, several problems have been reported with these treatments. Serious complications after photodynamic therapy for PCV were reported, such as massive subretinal hemorrhage and retinal atrophy. With anti-VEGF therapy, polypoidal lesions regressed in only 40% of the cases. Hence, prolonged treatment might be required for PCV. With prolonged use of ranibizumab, diminution of biological effects adversely affect long-term efficacy. One possible mechanism of diminution is tachyphylaxis, which is defined as phenomena causing reduced drug efficacy by repeated administration. The chance of developing tachyphylaxis was 2% after intravitreal ranibizumab (IVR) for age-related macular degeneration (AMD), and prevention of tachyphylaxis was important for long-term therapeutic effects against PCV.

One possible countermeasure for tachyphylaxis is cessation of drug treatment, however, discontinuation of the treatment might result in irreversible retinal damage by deterioration from PCV. Another possible countermeasure for tachyphylaxis is...
introduction of a drug with a different mechanism of action. Aflibercept (Eylea; Regeneron, Tarrytown, PA, USA and Bayer HealthCare, Berlin, Germany) is a recombinant soluble decoy receptor fusion protein. In contrast to the antibody-based VEGF binding strategy used by ranibizumab, aflibercept incorporates the second binding domain of the VEGF receptor-1 and the third domain of the VEGF receptor-2. The binding affinity of intravitreal aflibercept (IVA) to VEGF is higher than that of ranibizumab. A rapid improvement after conversion to aflibercept from ranibizumab was reported for eyes with chronic refractory AMD. Conversion to aflibercept might be a prospective countermeasure for ranibizumab tachyphylaxis in PCV. In this study, we evaluated the visual and anatomical response of IVA in eyes with PCV after development of ranibizumab tachyphylaxis, and evaluated therapeutic effects 3 months after conversion from ranibizumab to aflibercept.

Material and methods

This retrospective study was performed according to the tenets of the Declaration of Helsinki and was approved by the Institutional Review Boards of Tokyo Medical University and Ibaraki Medical Center. Informed consent for the examination was obtained from all patients. At each visit, all patients received a comprehensive ophthalmologic examination, including best-corrected visual acuity (BCVA), indirect ophthalmoscopy, slit-lamp biomicroscopy with a contact lens, fundus photography, and optical coherence tomography (OCT: 3D OCT-2000; Topcon, Tokyo, Japan). Central retinal thickness (CRT) was measured using an OCT B-scan image.

The clinical diagnosis of PCV was made by identification of polypoidal lesions with indocyanine green angiography. All eyes were initially treated with three consecutive intravitreal injections of 0.5 mg ranibizumab every 4 weeks. An additional IVR was given if any of the following changes were observed: (1) any serous retinal detachment, (2) increasing intraretinal fluid, (3) enlargement of a pigment epithelial detachment, and (4) new macular hemorrhages.

All eyes were converted to intravitreal injection of 2 mg aflibercept after diagnosis of ranibizumab tachyphylaxis. Tachyphylaxis was defined as the phenomenon in which the repeated intravitreal ranibizumab resulted in a complete lack of response after initial treatment response. Initial treatment response was defined as complete resolution of intra/subretinal fluid and pigment epithelial detachment after the initial treatment regimen. Lack of response was considered as an increase in intra/subretinal fluid or pigment epithelial detachment despite two or more intravitreal injections of ranibizumab. After an initial single injection of aflibercept, all eyes were examined every 4 weeks. Retreatment was applied according to the same protocol for intravitreal ranibizumab, at every 4 weeks, and retreatment was applied at least every 8 weeks, regardless of the findings.

For statistical analysis, BCVA, as measured with a Landolt chart, was converted to a logarithm of the minimal angle of resolution. CRT was manually measured using an OCT B-scan image. The BCVA and CRT were compared at baseline, at complete resolution after IVR, at reactivation after IVR, at initial IVA, and at 4 and 12 weeks after initial IVA. Statistical significance was calculated using a Wilcoxon signed-rank test and defined as \( P < 0.05 \). Statistical software (Statview 5.0; SAS Institute, Cary, NC, USA) was used for statistical analyses.

Results

This study included ten eyes of ten Japanese patients (seven males, three females) with PCV, ranging from 61 years to 85 years of age (mean: 73.3 years). All eye treatments were converted from ranibizumab to aflibercept because of ranibizumab tachyphylaxis. The mean greatest linear dimension at baseline was 3925 \( \mu m \) (range 850–7600 \( \mu m \)) based on fluorescein angiography, and 2830 \( \mu m \) (range 800–4600 \( \mu m \)) based on indocyanine green angiography. The mean BCVA at baseline was significantly improved at the initial treatment response by IVR (\( P = 0.025 \), Table 1). The mean CRT at baseline was significantly reduced at the initial treatment response period (\( P = 0.008 \), Table 1). The mean number of IVR for initial inactivation was 3.4 (range 3–5).

The mean number of IVR at reactivation was 7.9 (range 4–14), and the mean duration from initial IVR was 308 days (range 105–518 days). The mean CRT at reactivation was increased from the initial treatment response (\( P = 0.09 \), Table 1). After reactivation, the mean CRT was increased.

Table 1 Treatment response to ranibizumab and aflibercept

| Stage of reactivation | Mean visual acuity (logMAR) | Mean central retinal thickness (\( \mu m \)) |
|-----------------------|-----------------------------|-------------------------------------------|
| Baseline (SD)         | 0.53 (0.39)                 | 469 (148)                                 |
| Stage of inactive disease (SD) | 0.32 (0.35)             | 258 (76)                                  |
| Stage of reactivation (SD) | 0.35 (0.20)               | 341 (130)                                 |
| Day of conversion to intravitreal aflibercept (SD) | 0.35 (0.32) | 385 (119) |
| 4 weeks after conversion (SD) | 0.31 (0.32)           | 183 (48)                                  |
| 12 weeks after conversion (SD) | 0.36 (0.31)           | 223 (95)                                  |

Abbreviations: logMAR, logarithm of the minimal angle of resolution; SD, standard deviation.
(P = 0.11, Table 1) despite monthly IVR (mean 4.4 injections, range 2–8 injections). All eyes were judged with ranibizumab tachyphylaxis based on complete lack of response, and were converted to IVA. Mean number of IVR before conversion to IVA was 11.3 (range 5–16). Indocyanine green angiography images at conversion to IVA showed polypoidal lesions in nine of ten eyes (Figure 1), and polypoidal lesion could not be detected in one eye. At 4 weeks after a single injection by IVA, OCT findings were improved in all eyes (Figure 1), and mean CRT was significantly reduced from time of first IVA (P = 0.005, Table 1). In the 12 weeks after conversion to IVA, three injections by IVA were applied to one eye, and two injections by IVA were applied to nine eyes. The mean CRT at 12 weeks after conversion was significantly reduced from the time of first IVA (P = 0.005, Table 1). In one eye with three injections, intra/subretinal fluid was gradually decreased throughout the observation period, and intra/subretinal fluid disappeared at 12 weeks after the first IVA. Among the eyes with two injections, five eyes showed increased intra/subretinal fluid at 8 weeks after IVA, and intra/subretinal fluid disappeared again at 4 weeks after retreatment. In the other four eyes with two injections, retreatment was applied at 8 week intervals without any recurrences. No significant changes in the mean BCVA were observed throughout the follow-up after initial treatment response.

**Discussion**

Ranibizumab was approved by the United States Food and Drug Administration in December 2005, and ranibizumab became a mainstay for the treatment of AMD.11 In contrast,
aflibercept was approved in November 2011, and accordingly, clinicians have only limited clinical experience with aflibercept compared to ranibizumab. The predicted biological activity of aflibercept is higher than ranibizumab, hence, aflibercept is used as a rescue drug for refractory AMD with ranibizumab. In this study, switching to aflibercept resulted in significant improvement in anatomical outcome in eyes with PCV with ranibizumab tachyphylaxis.

After approval of ranibizumab, monotherapy with ranibizumab became a leading therapeutic modality for AMD. Eyes with AMD might receive repeated IVR for a long time, and thereby the risk of tachyphylaxis or tolerance may potentially increase. In our study, all cases showed increases in intra/subretinal fluid or pigment epithelial detachment despite repeated intravitreal ranibizumab, which could be considered as tachyphylaxis rather than tolerance. One possible mechanism of ranibizumab tachyphylaxis is the development of emerging anti-ranibizumab antibodies. To prevent antibody development, use of drugs with different molecular structure could be an effective alternative. Switching the treatment to bevacizumab achieved 81% success rate after development of ranibizumab tachyphylaxis for AMD. In our study, conversion to aflibercept showed better success rates than bevacizumab. Bevacizumab and ranibizumab have similar protein structures. In contrast, aflibercept has a different molecular structure than ranibizumab, and this dissimilarity might produce a better success rate than bevacizumab.

Another possible mechanism of ranibizumab tachyphylaxis is the presence of another pathway other than the VEGF-A family. VEGF-A is the target of ranibizumab, and this dissimilarity could be related to the activities of PCV vascular lesions. Photodynamic therapy might be an additional procedure to evaluate in treatment regimens. Further studies are required to establish the strategy of aflibercept treatment for PCV.

Conclusion

In conclusion, conversion to aflibercept is effective for PCV after development of ranibizumab tachyphylaxis.
