Test of Einstein-Podolsky-Rosen Steering Based on the All-Versus-Nothing Proof

Chunfeng Wu1,2, Jing-Ling Chen1,3, Xiang-Jun Ye1,3, Hong-Yi Su1,3, Dong-Ling Deng4, Zhenghan Wang5 & C. H. Oh1,6

In comparison with entanglement and Bell nonlocality, Einstein-Podolsky-Rosen steering is a newly emerged research topic and in its incipient stage. Although Einstein-Podolsky-Rosen steering has been explored via violations of steering inequalities both theoretically and experimentally, the known inequalities in the literatures are far from well-developed. As a result, it is not yet possible to observe Einstein-Podolsky-Rosen steering for some steerable mixed states. Recently, a simple approach was presented to identify Einstein-Podolsky-Rosen steering based on all-versus-nothing argument, offering a strong condition to witness the steerability of a family of two-qubit (pure or mixed) entangled states. In this work, we show that the all-versus-nothing proof of Einstein-Podolsky-Rosen steering can be tested by measuring the projective probabilities. Through the bound of probabilities imposed by local-hidden-state model, the proposed test shows that steering can be detected by the all-versus-nothing argument experimentally even in the presence of imprecision and errors. Our test can be implemented in many physical systems and we discuss the possible realizations of our scheme with non-Abelian anyons and trapped ions.

In 1935, Einstein, Podolsky, and Rosen (EPR) questioned the completeness of quantum mechanics (QM) based on local realism1. Many efforts have been devoted to a deeper understanding of QM in the form of three types of quantum nonlocalities: quantum entanglement, EPR steering, and Bell nonlocality2. Within the hierarchy of nonlocalities, the set of EPR steerable states is a subset of entangled states and a superset of Bell nonlocal states. Quantum entanglement and Bell nonlocality have attained flourishing developments since 1964. However, EPR steering is a newly emerged research topic and, to date, is far from being completely understood. Steering inequalities for EPR steering are the analog of Bell inequalities for Bell nonlocality. Their violations, predicted by quantum mechanics, reveal EPR steering. Such a violation rules out the existence of a local-hidden-state (LHS) model, the same way the violation of a Bell inequality rules out the existence of a local-hidden-variable (LHV) model. In comparison to the development of Bell nonlocality, the research on EPR steering is in its developing stages, even though Schrödinger discussed the concept in 19353. A reason for this is the absence of a rigorous formulation of the concept of EPR steering, which did not appear until the work of Wiseman, Jones, and Doherty4 in 2007. Indeed, EPR steering answers a question of fundamental quantum physics as well as opens new possibilities for quantum communication, thus it has inspired some recent research in quantum information theory5.

For a pure entangled state shared by two separated observers Alice and Bob, Bob’s qubit can be “steered” into different states although Alice has no access to the qubit. Schrödinger adopted the word steering to describe this type of nonlocality. This means that Alice has the ability to remotely prepare Bob’s particle in different states by measuring her particle using different settings, and here we use $\hat{\rho}_A^a$ to denote the conditional state Bob gets if Alice measures her particle with measurement $A$ and obtains result $a$. While Bob suspects that Alice may send him some non-entangled particles and fabricate the results based her knowledge of LHS. If Bob’s system admits a LHS model $\{\varphi_{\xi}\}$ where $\varphi_{\xi}$’s are states that Bob does not know (but Alice knows), and $\varphi_{\xi} > 0$ is the probability of $\rho_{\xi}$, then Alice could attempt to fabricate the results using her knowledge of $\xi$, in other words, $\hat{\rho}_A^a = \sum_{\xi} \varphi(a|A,\xi) \varphi_{\xi} \rho_{\xi}$, with $\sum_{\xi} \varphi(a|A,\xi) = 1$. If Bob finds there is a LHS model which can describe his
The document discusses the detection of EPR steering and its experimental implementation in various physical systems. It presents a method for testing EPR steering using a family of two-qubit states and demonstrates the feasibility of detecting asymmetric steering. The text also outlines a scheme for testing EPR steering based on the AVN proof and highlights the role of quantum gates and state readout in facilitating this detection.

Results:

First, an experimental setup is described where Alice and Bob share a pure entangled state $|\Psi_{AB}\rangle = \cos \theta |00\rangle_{AB} + \sin \theta |11\rangle_{AB}$. In the steering scenario, Alice performs projective measurements in $z$- and $x$-directions, and after her measurements, the conditional states for Bob are:

$$
\begin{align*}
\tilde{\rho}_B^0 &= \cos^2 \theta |0\rangle_B \langle 0|, \\
\tilde{\rho}_B^1 &= \sin^2 \theta |1\rangle_B \langle 1|, \\
\rho_B^0 &= \frac{1}{2} |\psi\rangle_B \langle \psi|, \\
\rho_B^1 &= \frac{1}{2} |\phi\rangle_B \langle \phi|,
\end{align*}
$$

where $\rho_B^a$ describes Bob's state after Alice performs measurement $a$ and obtains result $a$, and $|\psi\rangle_B = \cos \theta |0\rangle_B + \sin \theta |1\rangle_B$ and $|\phi\rangle_B = \cos \theta |0\rangle_B - \sin \theta |1\rangle_B$. A suitable ensemble $\{\rho_B^a\}$ and a stochastic map $\varphi(a|\tilde{A},\tilde{z})$ satisfying $\tilde{\rho}_B^a = \sum_{\tilde{z}} \varphi(a|\tilde{A},\tilde{z}) \varphi_{\tilde{z}} \rho_{\tilde{z}}$, then Bob is not convinced that Alice can steer his conditional states. Otherwise, the LHS model contradicts with QM.

According to the AVN proof, the entangled state $|\Psi_{AB}\rangle$ cannot be described by any LHS model except $\theta = 0$ or $\pi/2$. The incisive contradiction between QM and LHS model is due to different predicted projective probabilities as stated in the following. For QM, Bob obtains zero probabilities after he performs some appropriate projective measurements on his qubit:

$$
\begin{align*}
P_{1QM}^{QM} &= \text{Tr} |1\rangle_B \langle 1| \rho_B^0 = 0, \\
P_{2QM}^{QM} &= \text{Tr} |0\rangle_B \langle 0| \rho_B^1 = 0, \\
P_{3QM}^{QM} &= \text{Tr} |\psi\rangle_B \langle \psi| \rho_B^0 = 0, \\
P_{4QM}^{QM} &= \text{Tr} |\phi\rangle_B \langle \phi| \rho_B^1 = 0,
\end{align*}
$$

where $|\psi\rangle_B = \sin \theta |0\rangle_B - \cos \theta |1\rangle_B$ and $|\phi\rangle_B = \sin \theta |0\rangle_B + \cos \theta |1\rangle_B$. The test is fault-tolerant to anyons being moved. Therefore, the test is fault-tolerant to errors from slight imprecisions in the way that anyons are moved. The test is also applicable to many other physical systems, such as photons, atoms as well as superconductors, etc. In a system of non-Abelian Fibonacci anyons, each logical qubit is encoded into triplet of Fibonacci anyons and the corresponding operations are carried out by braiding the anyons. As braids are performed by taking an anyon either around another or not, which will not cause small errors from slight imprecisions in the way that anyons are moved. The test is fault-tolerant to errors and offers high experimental precision. In an ion-trap experiment, present experimental achievements on high-fidelity state initialization, quantum gates and state readout make our scheme of testing EPR steering possibly testable.

In an ideal test for EPR steering, after Alice performs projective measurements on her qubit of the state $|\Psi_{AB}\rangle$, Bob then measures the projective probabilities as stated in the following. For QM, Bob obtains zero probabilities after he performs some appropriate projective measurements on his qubit:

$$
\begin{align*}
P_{1LHS}^{LHS} &= \text{Tr} |1\rangle_B \langle 1| \sum _{\tilde{z}} \varphi(a=0|\tilde{z},\tilde{z}) \varphi_{\tilde{z}} \rho_{\tilde{z}}, \\
P_{2LHS}^{LHS} &= \text{Tr} |0\rangle_B \langle 0| \sum _{\tilde{z}} \varphi(a=1|\tilde{z},\tilde{z}) \varphi_{\tilde{z}} \rho_{\tilde{z}}, \\
P_{3LHS}^{LHS} &= \text{Tr} |\psi\rangle_B \langle \psi| \sum _{\tilde{z}} \varphi(a=0|\tilde{x},\tilde{z}) \varphi_{\tilde{z}} \rho_{\tilde{z}}, \\
P_{4LHS}^{LHS} &= \text{Tr} |\phi\rangle_B \langle \phi| \sum _{\tilde{z}} \varphi(a=1|\tilde{x},\tilde{z}) \varphi_{\tilde{z}} \rho_{\tilde{z}}.
\end{align*}
$$

From the AVN proof, we know that the state $|\Psi_{AB}\rangle$ possesses EPR steering if $\theta \neq 0$ or $\pi/2$, and this tells us there exists no LHS model of the state such that $\rho_B^a = \sum_{\tilde{z}} \varphi(a|\tilde{A},\tilde{z}) \varphi_{\tilde{z}} \rho_{\tilde{z}}$. When $\theta = 0$ or $\pi/2$, the state is separable, and hence it is possible to find a LHS model to describe it. Therefore, we know that the probabilities (3) cannot be zero simultaneously except $\theta = 0$ or $\pi/2$.

In an ideal test for EPR steering, after Alice performs projective measurement on her qubit of the state $|\Psi_{AB}\rangle$, Bob then calculates the probabilities by projecting the states $|0\rangle_B$ and $|\psi\rangle_B$ and $|\phi\rangle_B$ on his qubits. If he finds the four probabilities $P_i^{LHS}$ ($i = 1, 2, 3, 4$) are all zero, then EPR steering is demonstrated. Nevertheless, in real experiments (Exp), measurement results are inevitably affected by experimental precision and errors. It is possible that the probabilities obtained experimentally may deviate from the theoretical values slightly, i.e., $P_i^{Exp} = P_i^{QM} + \epsilon_i$. We then investigate how close a LHS model could be to simulate Eq. (2). We have shown that for the state $|\Psi_{AB}\rangle$, the probabilities $P_i^{LHS} = 0$ ($i = 1, 2, 3, 4$) only if the state shared by Alice and Bob is not steerable, otherwise, some of $P_i^{LHS}$ cannot be zero. For the sake of simplicity, consider the inevitable errors $\epsilon_i = \epsilon$ for all $i$, we can detect steerability if $P_i^{LHS} > \epsilon$ for some $i$. Therefore, the optimal LHS model for this experiment is the one making $P_i^{LHS}$ approach to $P_i^{QM}$ as closely as possible for all $i$. We define

$$
\Delta = \min_{LHS} \left\{ \max_{i \in \{1, 2, 3, 4\}} \left\{ \left| P_i^{LHS} - P_i^{QM} \right| \right\} \right\},
$$

where $\Delta$ describes the bound of probabilities imposed by the optimal LHS model. In our test, EPR steering can be detected when $\Delta > \epsilon$. Fig. 1(a) shows the relation between parameter $\theta$ and $\Delta$ obtained numerically (see the Methods section). We find that $\Delta$ is of order $10^{-2}$ when $\theta$ is not closed to 0 or $\pi/2$. This implies that the EPR steering of state $|\Psi_{AB}\rangle$ can be revealed by the experiments with precision $\epsilon < 10^{-2}$. In Fig. 1(a), it is observed that $\Delta$ changes symmetrically with respect to $\theta$ and approaches to its maximal value.
when $\theta = \pi/4$. This shows the more entangled the state is, the easier to detect EPR steering in the experiment.

We next consider a two-qubit mixed state

$$\rho_{AB} = \cos^2 \theta |\psi^+\rangle_{AB} \langle \psi^+ | + \sin^2 \theta |\phi^+\rangle_{AB} \langle \phi^+ |. \tag{5}$$

Here

$$|\psi^+\rangle_{AB} = \frac{1}{\sqrt{2}} (|00\rangle_{AB} + |11\rangle_{AB})$$

and

$$|\phi^+\rangle_{AB} = \frac{1}{\sqrt{2}} (|01\rangle_{AB} + |10\rangle_{AB})$$

are two Bell states. The measurement settings of Alice are still $\mathcal{A} \in \{D^a, T^a\}$, and after Alice performs measurement $\mathcal{A}$ and obtains result $a$, Bob’s conditional states can be expressed as $\tilde{\rho}^a_B = \sum_z \varphi(a|\tilde{\rho}^z|_B^a\rangle_{AB}$ provided with a LHS model $\{\varphi_1, \varphi_2\}$ and a stochastic map $\varphi$ $(a|\tilde{\rho}^z|_B^a\rangle_{AB}$). Similarly, for the state $\rho_{AB}$, Bob obtains quantum probabilities of measuring his qubit in the states $|0\rangle_B, |1\rangle_B, |+\rangle_B$ and $|-\rangle_B$ as

$$P_{1}\text{OM} = \text{Tr} (|1\rangle_B\langle 1| \tilde{\rho}^z) = \frac{\sin^2 \theta}{2},$$

$$P_{2}\text{OM} = \text{Tr} (|0\rangle_B\langle 0| \tilde{\rho}^z) = \frac{\sin^2 \theta}{2},$$

$$P_{3}\text{OM} = \text{Tr} (-|\tilde{\rho}^z) = 0,$$

$$P_{4}\text{OM} = \text{Tr} (|+\rangle_B\langle +| \tilde{\rho}^z) = 0,$$\tag{6}

where $|\pm\rangle_B = \frac{1}{\sqrt{2}} (|0\rangle_B \pm |1\rangle_B)$, and $\tilde{\rho}^z$ is Bob’s conditional state after Alice performs projective measurement in $z$-direction, etc. It has been proved that there does not exist any LHS model for $\rho_{AB}$ with $\theta \neq \frac{\pi}{4}$ such that probability equations in (6) can be satisfied simultaneously. If Bob observes experimentally these four probabilities $P_{1-4}\text{OM}$’s, then EPR steering of the state is exhibited, or there exists no LHS model. Consider experimental imprecision and errors, we also investigate the condition to detect EPR steering of $\rho_{AB}$ by plotting the variation of LHS bound $\Delta$ versus $\theta$, see Fig. 1 (b). It can be found that for the experiments with precision $\varepsilon < 10^{-5}$, the EPR steering of $\rho_{AB}$ can be observed when $\theta$ is not close to $\pi/4$. It is worthy of pointing out that our test of EPR steering is not limited to the states $|\Psi\rangle_{AB}$ and $\rho_{AB}$, but also applicable to the family of two-qubit entangled states specified in Ref. 12, regardless of pure or mixed.

Discussions

Let us make some discussions on the possible realization of our test in physical systems. We first consider non-Abelian Fibonacci anyons which are shown to be the simplest non-Abelian quasiparticles for universal topological quantum computation\textsuperscript{14}. Follow Freedman et al.’s work\textsuperscript{25}, we encode logical qubits into triplets of anyons with total topological charge $1$: $|0\rangle^L = |(\cdot, \cdot)\rangle$, and $|1\rangle^L = |(\cdot, \cdot, \cdot)\rangle$ (here $L$ denotes “logical”). The so-called noncomputational state $|\text{NC}\rangle = |(\cdot, \cdot)\rangle$ is the only state of three anyons that has total topological charge 0. Quantum operations can be constructed by using two elementary braiding operations $R_1, R_2$ acting on the Hilbert space of three Fibonacci anyons and their inverses\textsuperscript{26,27}. The obtained quantum gates, together with the controlled-NOT gate obtained in Refs. 16–18 are useful in the construction of EPR steering test by preparing logical-qubit states and achieving required operations (see the Methods section). Several candidates for realizing non-Abelian anyons have been suggested in physical systems, such as fractional quantum Hall liquid\textsuperscript{20}, rotating Bose-Einstein condensates\textsuperscript{28}, as well as quantum spin systems\textsuperscript{21,22}.

Another possible system to explore the realization of our test experimentally is trapped ion. Refs. 23–25 have reported experimental results of high-fidelity state preparation, quantum gate operations, and state measurement for optical qubits stored in $^{40}\text{Ca}^+$ held in a trap. State preparation is usually done by precisely manipulating the internal levels of ion utilizing laser pulses and the Blatt group realized state initialization with fidelity more than 99.8%\textsuperscript{24}. By a Mølmer-Sørensen-type gate operation\textsuperscript{26,27}, a Bell-type entangled state of ions with a fidelity of 99.3(1)% was realized in the same work\textsuperscript{24}. The Blatt group also presented single-qubit gates with fidelity exceeding 99.9% in trapped ions\textsuperscript{25}. As for state measurement capability in an ion-trap experiment, A. H. Myerson et al.\textsuperscript{23} achieved 99.99(1)% readout fidelity, sufficient for fault-tolerant quantum computation by measuring population of states using time-resolved photon counting. For the entangled state realized in Ref. 24, the probability bound is found to be $\Delta = 0.0732$, and this means that the EPR steering of the entangled state can be verified experimentally with precision $\varepsilon < 0.0732$. The experimental achievements in the literatures\textsuperscript{23–25} tell us that our test of EPR steering based on the AVN proof is possibly realizable with current techniques in ion-trap experiments.

To summarize, we have presented a test to identify EPR steering based on the AVN argument by measuring projective probabilities. Our test is applicable to the family of two-qubit entangled states specified in Ref. 12 regardless of pure or mixed. We have provided the condition on experimental implementation of our scheme through expression (4) that EPR steering can be observed in the presence of experimental imprecision and errors. Our result is the first experimental test presented to detect EPR steering by resorting to the AVN proof, and it can be implemented in systems such as non-Abelian anyons and trapped ions. The primary advantage of our test based on non-Abelian anyons is that it is fault-tolerant, or the logical quantum state used is robust against local perturbations.
We next check each limited to the two systems but also applicable to many other physical quantum gate operations, and state measurement for optical qubits experiments based on current experimental techniques as recent progress in trapped ion high-fidelity state preparation, quantum gate operations, and state measurement for optical qubits stored in it. Let us point out that the realization of our test is not limited to the two systems but also applicable to many other physical systems like photons, atoms and superconductors, etc. We expect further investigations in this direction, both theoretically and experimentally.

Methods

To find the optimal LHS model. We here present a theorem which is used to find the optimal LHS model for a given two-qubit state. Theorem – For any given two-qubit state $\rho_{AB}$ in a $N$-setting protocol, if there is a LHS model for the state, then there is a LHS model with the number of hidden states no larger than $2^N$. The proof of the Theorem needs two lemmas associated with the concept of deterministic LHS (dLHS) model which is a LHS satisfying $\psi(a|A,\xi)\in\{0,1\}$, $\forall A,\xi$. We also briefly restate the notation to be used, $\rho_{s}^{m}$ is the conditional states of Bob after Alice measures $A$ and gets result $s\in\{0,1\}$, the tilde here denotes this state is unnormalized and its norm is $P_{s}^{m}$, the probability associated with the output $a$.

Lemma 1. For any given two-qubit state $\rho_{AB}$, if there is a LHS model for $\rho_{AB}$, then there is a dLHS model for $\rho_{AB}$.

In a general $N$-setting protocol, we have $A\in\{\hat{A}_{1},\hat{A}_{2},\ldots,\hat{A}_{N}\}$. Suppose $\rho_{AB}$ has a LHS description thus there is an ensemble $(\rho,\psi_{s})$ and an associated probability $\psi(a|A,\xi)$ fulfilling $\rho_{s}^{m} = \sum_{\xi} \psi(a|A,\xi) \psi_{s}$. We note that $\psi(1|A,\xi) = 1 - \psi(0|A,\xi)$. Now if $\xi,\hat{A}_{1},\ldots,\hat{A}_{N} \in \{0,1\}$, then it is a dLHS model. We next check each $\xi$ to see whether $\psi(0|A,\xi)\in\{0,1\}$. For any $\xi$ with $\psi(0|A,\xi)\in\{0,1\}$, we keep these terms unchanged. For $\xi = k|\psi(0|A,\xi)\neq\{0,1\}$, we decompose this term into $2^{n_i}$ separate terms as follows. First we define a new term $m_{a} = \sum_{i=1}^{N} 2^{N-i}a_{i} + 1$, where $a_{i}$ denote the measurement results of $\hat{A}_{i}$ ($a_{i} = 0, 1$). It is not difficult to find that $m_{a}$ ranges from 1 to $2^{N}$ depending on $a$. We then do the decomposition by choosing

$$\rho_{k}^{(m_{a})} = \rho_{k},$$

$$\psi(0|\hat{A}_{a},k^{(m_{a})}) = \begin{cases} 1 & \text{if } a_{i} = 0 \\ 0 & \text{else} \end{cases}$$

where $\rho_{k}^{(m_{a})}$ is the hidden state and $\psi^{(m_{a})}$ is its weight. By direct calculations it can be verified that $\psi(a|\hat{A}_{a},k)\rho_{k} = \sum_{i=1}^{N} \psi(a|\hat{A}_{a},k)\psi_{i}^{(m_{a})}$. Eq. (9) shows the reconstructed stochastic maps are all deterministic. Thus by this way, we get a dLHS model that satisfies $P_{s}^{m}$.

Lemma 2. For a dLHS model, $\rho_{s}^{m} = \sum_{\xi} \psi(a|\hat{A}_{a}) \psi_{s}$, can be rewritten as

$$P_{s}^{m} = \sum_{\xi} \psi_{s} \xi,$$

$$P_{s}^{m} = \sum_{\xi} \psi_{s} \xi + \sum_{\xi} \psi_{s} \xi'$$

where $\xi$ and $\xi'$ are the Bloch vectors of $\rho_{s}^{m}$ and $\rho_{s}$ respectively.

Let us look at the proof of the lemma. We have $\rho_{s}^{m} = (1 + \xi)^{2}/2$ and $\rho_{s} = (1 + \xi')^{2}/2$, where $1$ describes identity matrix. So the equality of $P_{s}^{m}$ and $P_{s}$ gives $P_{s}^{m} + P_{s}^{m} \xi = \xi' \xi'$. Thus we obtain Eq. (10).

We would like to point out that Eq. (10) is similar to the problem describing center of mass if we treat the probabilities $\psi_{s}$ and $P_{s}^{m}$ as masses, as well as Bloch vectors ($\xi$ and $\xi'$) as the position vectors of various masses. Lemma 2 shows that the task to find a dLHS model for a state $\rho_{s}^{m}$ with probability $P_{s}^{m}$ is equivalent to find a distribution of masses in the Bloch sphere with total mass $P_{s}^{m}$ and center of mass being located at $\xi^{\prime}$. We show in the following that with the aid of Eq. (10), we can impose constraints on measurement settings to find a dLHS model. If we cannot find a dLHS model for $\rho_{AB}$, Lemma 1 shows that we can neither find a LHS model, and this thus affirms the steerability of $\rho_{AB}$. For any given $\rho_{AB}$, we can always assign a $N$-length bit string constructed from $\psi(a|\hat{A}_{a})$, $\rho_{AB}$ into many subsets with each subset containing all of the $\rho_{i}$ that has the same $N$-length bit string. Thus in this way, each subset is unique, or not overlapping with others. We can take each of the subsets as one new hidden state by resorting to Lemma 2. We use the fact that hidden state can be treated as mass point so we can consider the centre of mass of each subset as the new state and the weight of the new state is the corresponding total mass. It is not difficult to find that there are totally $2^{N}$ such new states, and thus the LHS model has only $2^{N}$ hidden states. This ends our proof of the Theorem.

Figure 3 | Variations of $\Lambda$ for $|\Psi_{AB}\rangle$ versus $a/\theta$. (a) $\theta = \pi/8$ and $n$ ranges from 20 to 120, (b) $\theta = \pi/6$ and $n$ ranges from 20 to 120, as well as (c) $n = 46, 50, 100$ and $\theta$ ranges from 0 to $\pi/2$. From (a) and (b), we find that the variation of $\Lambda$ is negligibly small when $n > 45$ since the variation is in the thousandths place. From (c) it is clear that the three curves are almost overlapped and the results show that $n = 46$ is large enough to obtain a reasonable value of $\Lambda$. 
Therefore we conclude that the optimal LHS model contains an ensemble with four pure hidden states in the two-setting protocol, and more hidden states make no improvement. The optimal LHS model is numerically obtained by minimizing function $F_n = \sum_{n=1}^{4} v_n^2$ for a large $n$, where $v_n = |p^{AB}_{n} - p^{CD}_{n}|$. In this approach, we utilize the knowledge of vector norm. First we have $F_{n} = \sum_{n=1}^{4} v_n^2$ which is the $L_2$-norm of vector $v = (v_1, v_2, v_3, v_4)$. We know that $L_2$-norm of a vector is just its maximum element and hence by definition $\Delta$ equals to the minimum of $L_2$-norm of the vector $v = (v_1, v_2, v_3, v_4)$. So for a large enough $n$ we can get a good approximation of $\Delta$ from minimizing $F_{n}$. We find the values of $\theta$ by choosing $\theta = \frac{n}{n+6}$. We also plot the variation of $\Delta$ versus $\theta$ by changing different $n$ for $|\Psi_{AB}\rangle$ in Fig. 3 (c). Seen from Fig. 3 (c), the three curves corresponding to $n = 46$, $n = 50$, $n = 100$ respectively are almost overlapped. Hence we know that $n = 46$ is large enough to obtain a reasonable value of $\Delta$.

Approximation of quantum gates in non-Abelian Fibonacci anyons. Quantum operations can be constructed by using two elementary braiding operations $R_1$, $R_2$ acting on the Hilbert space of three Fibonacci anyons and their inverses\(^{33,37,38}\). In Fig. 2, we plot the braids that approximate the quantum gate

$$U_0 = \begin{pmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

with $U_0 = U_{2n}$, $U_1 = U_{2n+1}$. Any other quantum gate $U_0$ can be obtained in a similar way. The approximations are obtained by performing brute force searches and the distance between two matrices $U_{AB}$ and $U_{CD}$ is defined as the square root of the largest eigenvalues of $(U_{AB}^{-1} U_{CD})^\dagger (U_{AB}^{-1} U_{CD})$. The distances between the required operations and the gates resulting from actual braiding are about $5.7 \times 10^{-3}$ for $U_1$ and $U_2$. In fact, these gates can be systematically improved to any required accuracy due to the Solovay-Kitaev theorem\(^{28}\). The above quantum gates, together with the controlled-NOT gate obtained in Refs. 16–18 are useful in the construction of EPR steering by preparing logical-qubit states. We apply the operation $U_0$ with $\theta = (0, \pi/3)$ on the logical qubit $A$ of an initial state $|\Psi_{AB}\rangle_0 = |0\rangle_0 \otimes |0\rangle_0$ and a controlled-NOT gate is followed on the two logical qubits, then we have the two-logical-qubit pure states $|\Psi_{AB}\rangle_{0,0}$. To prepare mixed state, we need an ancilla logical qubit $C$, and initially assume that the logical qubits are in the state $|\Psi_{AB}\rangle_0 = |0\rangle_0 \otimes |0\rangle_0$. We apply Hadamard gate on logical qubit $A$, $U_0$ on logical qubit $C$, then a controlled-NOT gate on logical qubits $A$ and $B$, and finally a controlled-NOT gate on logical qubits $C$ and $B$ in the logical qubits $C$ and $B$. We then have $|\Psi_{AB}\rangle_{0,0} = \cos \theta |\psi^{+}\rangle^{\dagger} |0\rangle_0 + \sin \theta |\psi^{+}\rangle^{\dagger} |1\rangle_0$. Look at the first two qubits only, we successfully have the state $p_{AB,0,0,0}$ (as in (5)). All the operations involved in our scheme, such as $P_A$ and $P_C$ for Alice, $|\psi^{+}\rangle^{\dagger}$ and $|\psi^{-}\rangle^{\dagger}$ for Bob, can be carried out by braiding the Fibonacci anyons. For instance, the single-logical-qubit states $|\psi^{+}\rangle_{AB}$ and $|\psi^{-}\rangle_{AB}$ of Bob can be realized by using the action of $U_{0,0,0,0}$ on $|1\rangle_{A}$ (up to a global phase).
