ABSTRACT

We report the discovery of three extrasolar planets that transit their moderately bright ($m_V = 12–13$) host stars. WASP-44b is a 0.89-$M_{\text{Jup}}$ planet in a 2.42-day orbit around a G8V star. WASP-45b is a 1.03-$M_{\text{Jup}}$ planet which passes in front of the limb of its K2V host star every 3.13 days. Weak Ca II H&K emission seen in the spectra of WASP-45 suggests that the star is chromospherically active. WASP-46b is a 2.10-$M_{\text{Jup}}$ planet in a 1.43-day orbit around a G6V star. Rotational modulation of the light curves of WASP-46 and weak Ca II H&K emission in its spectra show the star to be photospherically and chromospherically active.

We imposed circular orbits in our analyses as the radial-velocity data are consistent with (near-)circular orbits, as could be expected from both empirical and tidal-theory perspectives for such short-period, ~Jupiter-mass planets. We discuss the impact of fitting for eccentric orbits for such planets when not supported by the data. The derived planetary and stellar radii depend on the fitted eccentricity and these parameters inform intense theoretical efforts concerning tidal circularization and heating, bulk planetary composition and the observed systematic errors in planetary and stellar radii. As such, we recommend exercising caution in fitting the orbits of short-period, ~Jupiter-mass planets with an eccentric model when there is no evidence of non-circularity.

Key words: planets and satellites: individual: WASP-44b – planets and satellites: individual: WASP-45b – planets and satellites: individual: WASP-46b – stars: individual: WASP-44 – stars: individual: WASP-45 – stars: individual: WASP-46.

1 INTRODUCTION

The ensemble of well-characterized transiting extrasolar planets is growing at pace, with well over 100 known to date. It is important to determine the system parameters accurately so that the inferences based on them are reliable. For example, to determine the bulk composition of a planet it is necessary to measure accurately its radius (e.g. Fortney, Marley & Barnes 2007). Many short-period, giant planets (e.g. WASP-17b; Anderson et al. 2010, 2011b) are larger than predicted by standard cooling theory of irradiated, gas-giant planets (e.g. Fortney et al. 2007). One potential explanation is that energy from the tidal circularization of eccentric orbits was dissipated within the planets’ interiors, causing them to bloat (e.g. Bodenheimer, Lin & Mardling 2001). To evaluate the likelihood that a planet was inflated by such tidal heating, it is necessary to have an accurate determination of both its radius and its orbital eccentricity (e.g. Ibgui, Spiegel & Burrows 2011).

A planet’s orbital eccentricity can be determined by measuring the radial motion of its host star around its orbit (e.g. Queloz et al. 2010), or by observing occultations of the planet by its host star (e.g. Anderson et al. 2011b), or from a combination of the two. By combining this eccentricity measurement with high-quality transit light curves, we can measure a star’s density (Seager & Mallén-Ornelas 2003). The stellar mass can be estimated using stellar evolution models (e.g. Demarque et al. 2004) or mass-calibration laws (e.g. Torres, Andersen & Giménez 2010), and the stellar radius follows. This, combined with the ratio of the radii derived from the transit depth, gives the planet radius.

⋆E-mail: dra@astro.keele.ac.uk
In papers announcing new planet discoveries, eccentricity is often poorly determined, thus the planet radius can be uncertain. Despite this, there are theoretical (Goldreich & Soter 1966) and empirical (Pont et al. 2011) reasons to expect short-period (≤4 d), Jupiter-mass (∼0.5–2 M_Jup) planets, often referred to as hot Jupiters, to be in circular orbits. Thus, it is reasonable, in the absence of evidence to the contrary, to assume that a newly discovered hot Jupiter is in a circular orbit. In so doing, the derived stellar and planetary dimensions will be, on the whole, accurate.

In this paper we present three new hot Jupiters, WASP-44b, WASP-45b and WASP-46b, and discuss the effects of fitting an eccentric orbit model to a hot-Jupiter system in the absence of evidence for non-circularity.

2 OBSERVATIONS

2.1 Discovery photometry

The Wide Area Search for Planets (WASP) photometric survey (Pollacco et al. 2006) employs two eight-camera arrays, each with a field of view of 450 deg^2, to monitor bright stars (m_V = 8–15). Each array observes up to eight pointings per night with a cadence of 5–10 min, and each pointing is followed for around five months at a time. The WASP-South station (Hellier et al. 2011) is hosted by the South African Astronomical Observatory in South Africa and the SuperWASP-North station (Faedi et al. 2011b) is hosted by the Observatorio del Roque de Los Muchachos on La Palma. The WASP data were processed and searched for transit signals as described in Collier Cameron et al. (2006) and the candidate selection process is described in Collier Cameron et al. (2007).

WASP-44 is a m_V = 12.9, G8V star located in the constellation Cetus. A transit search of the light curve obtained by WASP-South from 2009 July to November found a weak, 2.42-d periodicity. Further observations in 2008 and 2009 with both WASP instruments led to a total of 15,755 photometric measurements (Fig. 1).

WASP-45 is a m_V = 12.0, K2V star located in the constellation Sculptor that was observed by WASP-South during 2006 May to November and 2007 May to November. A transit search of the resulting light curve, which comprises 11,007 photometric measurements, found a strong 3.13-d periodicity (Fig. 2).

WASP-46 is a m_V = 12.9, G6V star located in the constellation Indus that was observed by two WASP-South cameras during 2008 May to October and 2009 May to October. A transit search of the resulting light curve, which comprises 41,961 photometric measurements, found a strong 1.43-d periodicity (Fig. 3). WASP-46 was also observed by two WASP-South cameras during 2010 August to November. The resulting light curve comprises 19,000 measurements and became available during the preparation of this paper. As such, it was not used in the determination of the system parameters (Section 4), but was used in the search for rotational modulation (Section 5).

WASP-44 was also observed by a SuperWASP-North camera during 2010 August to November. The resulting light curve comprises 6,000 measurements and became available during the preparation of this paper. As such, it was not used in the determination of the system parameters (Section 4), but was used in the search for rotational modulation (Section 5).

Middle: WASP data around the transit, binned in time with a bin width of ~11 min. Bottom: high-precision transit light curves from Euler (upper) and TRAPPIST (lower).
2.2 Spectroscopic follow-up

In 2010 we used the CORALIE spectrograph mounted on the 1.2-m Euler-Swiss telescope (Baranne et al. 1996; Queloz et al. 2000) to obtain spectra of the three target stars. We obtained 17 spectra of WASP-44, 13 spectra of WASP-45 and 16 spectra of WASP-46. Radial-velocity (RV) measurements were computed by weighted cross-correlation (Baranne et al. 1996; Pepe et al. 2005) with a numerical G2-spectral template for both WASP-44 and WASP-46, and with a K5-spectral template for WASP-45. RV variations were detected with the same periods found from the WASP photometry and with semi-amplitudes consistent with planetary-mass companions. The RV measurements are listed in Table 1 and are plotted separately for each system in Figs 4–6. We excluded two RVs of WASP-44 from the analysis as the spectra were taken during transit and we do not fit for the Rossiter–McLaughlin effect (e.g. Simpson et al. 2011).

For each system we tested the hypothesis that the RV variations are due to spectral-line distortions caused by a blended eclipsing binary or star spots by performing a line-bisector analysis (Queloz et al. 2001) of the CORALIE cross-correlation functions. The lack of correlation between bisector span and RV (Figs 4–6) supports our conclusion that the periodic dimming and RV variation of each system are caused by a transiting planet.
Euler-Swiss telescope located at European Southern Observatory (ESO) La Silla Observatory, Chile to observe one transit each of WASP-44b, WASP-45b and WASP-46b. Observations were made through a Gunn \( r \) filter and Euler’s absolute tracking mode was used to keep the stars on the same location on the chip. This is done by calculating an astrometric solution for each science frame and adjusting the telescope pointing between exposures. After correcting the images for bias, overscan and flat-field variations, we extracted aperture photometry for the bright stars in the field. We selected the aperture radius and set of reference stars that resulted in the smallest light-curve residuals.

We used TRAPPIST,\(^1\) a 60-cm robotic telescope also located at ESO La Silla (Gillon et al. 2011) to observe one transit of WASP-45b and one transit of WASP-46b. Both transits were observed through a special \( I+z \) filter, in the 2-MHz readout mode, and with \( 1 \times 1 \) binning, resulting in a typical combined readout and overhead time of 8 s and a readout noise of 13.5 e\(^-\). The ‘software guiding’ system of TRAPPIST kept the stars at the same positions on the chip to within a few pixels over the course of the observations (Gillon et al., in preparation).

\subsection{2.3.1 WASP-44b}

A transit of WASP-44b was observed on 2010 September 14 by Euler. We observed for a total of 4.2 h, from 46 min before the start of the transit to 65 min after it ended. The conditions were clear, airmass ranged from 1.04 to 1.44 and no defocus was applied. The WASP-44b transit light curve is shown in Fig. 1 and the data are given in Table 2.

\subsection{2.3.2 WASP-45b}

A partial transit of WASP-45b was observed on 2010 September 11 by Euler. We observed for a total of 3.3 h, from partway through the transit to 2 h after it ended. The seeing was poor (1–2 arcsec) and airmass ranged from 1.01 to 1.22. We applied a defocus of 0.1 mm to increase the duty cycle and to minimize pixel-to-pixel effects.

A transit of WASP-45b was observed on 2010 December 17 by TRAPPIST. Observations lasted from 00:15 to 03:40 h UT, during

---

\(^1\) TRAnsiting Planets and Planetesimals Small Telescope; http://arachnos.astro.ulg.ac.be/Sci/Trappist.
which the airmass increased from 1.03 to 1.73 and the transparency was good. The telescope was strongly defocused to average pixel-to-pixel sensitivity variations and to increase the duty cycle, resulting in a typical full width at half-maximum (FWHM) of the stellar images of ~9 pixel (~5.8 arcsec). The integration time was 6 s. After a standard pre-reduction (bias, dark and flat-field correction), the stellar fluxes were extracted from the images using the IRAF/DAOPHOT\textsuperscript{2} aperture photometry software (Stetson 1987). We tested several sets of reduction parameters and chose the set that gave the most precise photometry for the stars of similar brightness to WASP-45. We carefully selected a set of reference stars and then performed differential photometry.

The WASP-45b transit light curves are shown in Fig. 2 and the data are given in Table 2.

2.3.3 WASP-46b

A transit of WASP-46b was observed on 2010 July 19 by TRAPPIST. Observations lasted from 01:15 to 04:05 UT, during which the airmass decreased from 1.83 to 1.22 and the transparency was good. Considering the relative faintness of the target, we chose to keep the telescope focused during the run, and we used an integration time of 60 s. The pre-reduction and reduction procedures were similar to those used for the WASP-45 data.

A transit of WASP-46b was observed on 2010 September 10 by Euler. We observed for a total of 3.4 h, from 35 min before the start of transit to 75 min after it ended. The conditions were variable and airmass increased from 1.12 to 1.4 during the observations. No defocus was applied.

The WASP-46b transit light curves are shown in Fig. 3 and the data are given in Table 2.

3 STELLAR PARAMETERS FROM SPECTRA

For each system, the CORALIE spectra were co-added to produce a single spectrum with a typical S/N of around 50:1. The analysis was performed using the methods given in Gillon et al. (2009). The Hα line was used to determine the effective temperature ($T_{\text{eff}}$), while the Na D and Mg b lines were used as surface gravity (log $g$) diagnostics. The parameters obtained from the analysis are given in Table 3. The elemental abundances were determined from equivalent width measurements of several clean and unblended lines. A value for microturbulence ($\xi_t$) was determined from Fe I using the method of Magain (1984). The quoted error estimates include that given by the uncertainties in $T_{\text{eff}}$, log $g$, and $\xi_t$, as well as the scatter due to measurement and atomic data uncertainties.

The projected stellar rotation velocities ($v \sin i$) were determined by fitting the profiles of several unblended Fe I lines. For this we used an instrumental FWHM of 0.11 ± 0.01 Å (= 5.2 ± 0.5 km s$^{-1}$), determined from the telluric lines around 6300 Å (equating to a spectral resolution of ~57 000), and used the Bruntt et al. (2010) calibration to assume values for macroturbulence ($v_{\text{mac}}$). The $v_{\text{mac}}$ values we assumed were 1.4 ± 0.3 km s$^{-1}$ for WASP-44, 0.7 ± 0.3 km s$^{-1}$ for WASP-45 and 2.0 ± 0.3 km s$^{-1}$ for WASP-46.

Though the S/N values are very low in the Ca II H&K regions of our spectra, we searched for signs of emission, which would be indicative of stellar chromospheric activity. The WASP-44 spectra show no signs of emission and both the WASP-45 and WASP-46 spectra show weak emission.

We input our values of $T_{\text{eff}}$, log $g$, and [Fe/H] into the calibrations of Torres et al. (2010) to obtain estimates of the stellar mass and radius.

We used the method of Barnes (2007) to estimate gyrochronological ages for the stars. For WASP-44 and WASP-45 we calculated

\begin{table}[h]

\end{table}
rotation periods from our $v \sin I$ determinations. If either star is inclined with respect to the sky plane then it will be rotating faster than suggested by $v \sin I$ and so is likely to be younger than indicated. For WASP-46, the rotation period found from the modulation of the WASP light curves was used (see Section 5). As such, the age estimate for this star is not just an upper limit.

4 SYSTEM PARAMETERS FROM RV AND TRANSIT DATA

4.1 WASP-44b and WASP-46b

We determined the parameters of each system from a simultaneous fit to all data. The fit was performed using the current version of the Markov chain Monte Carlo (MCMC) code described by Collier Cameron et al. (2007) andPollacco et al. (2008).

The transit light curves were modelled using the formulation of Mandel & Agol (2002) with the assumption that the planet is much smaller than the star. Limb darkening was accounted for using a four-coefficient, non-linear limb-darkening model, using coefficients appropriate to the passbands from the tabulations of Claret (2000, 2004). The coefficients were interpolated once using a four-coefficient, non-linear limb-darkening model, using coefficients appropriate to the passbands from the tabulations of Claret (2000, 2004).

We determined the parameters of each system from a simultaneous fit to all data. The fit was performed using the current version of the Markov chain Monte Carlo (MCMC) code described by Collier Cameron et al. (2007) andPollacco et al. (2008).

The transit light curves were modelled using the formulation of Mandel & Agol (2002) with the assumption that the planet is much smaller than the star. Limb darkening was accounted for using a four-coefficient, non-linear limb-darkening model, using coefficients appropriate to the passbands from the tabulations of Claret (2000, 2004). The coefficients were interpolated once using a four-coefficient, non-linear limb-darkening model, using coefficients appropriate to the passbands from the tabulations of Claret (2000, 2004).
At each step in the MCMC procedure, model transit light curves and RV curves are computed from the proposal parameter values, which are perturbed from the previous values by a small, random amount. The $\chi^2$ statistic is used to judge the goodness of fit of these models to the data and a step is accepted if $\chi^2$ is lower than for the previous step. A step with higher $\chi^2$ is accepted with a probability proportional to $\exp(-\Delta \chi^2/2)$, which gives the procedure some robustness against local minima and leads to the thorough exploration of the parameter space around the best-fitting solution.

To give proper weighting to each photometry data set, the uncertainties were scaled at the start of the MCMC so as to obtain a photometric reduced $\chi^2$ of unity. For the same reason, a jitter term was not necessary to add any jitter to the RVs of WASP-44.

### 4.2 WASP-45b

The analysis for WASP-45b was the same as for WASP-44b and WASP-46b, except we used evolutionary models to impose priors on stellar mass and density for reasons to be explained.

The apparent lack of the second and third contact points in the transit light curves of WASP-45b (Fig. 2) indicates that the transit is grazing or near-grazing. When $b + R_\text{pl}/R_\star > 1$, the planet does not fully pass in front of the star. Thus, as $b$ tends towards higher values, $R_\text{pl}/R_\star$ must inflate so that the ratio $R_\text{pl}/R_\star$ remains consistent with the observed transit depth. Also, $R_\star$ must inflate so as to remain consistent with the observed transit duration. This results in stellar and planetary radii that are non-physical in a sizeable portion of accepted MCMC steps.

To avoid biasing the derived stellar and planetary radii to larger values, we imposed a prior on stellar density using the constraints provided by our gyrochronological age determination (Table 3) and evolutionary models. Our gyrochronological age is determined using $v\sin i$ and so is an upper limit. If the stellar spin axis is inclined with respect to the sky plane then the star will truly be rotating faster and will therefore be younger. We plotted the isochrones and mass tracks of Demarque et al. (2004) relevant to the value ranges $\rho_\star = 1.65 \pm 0.40 \rho_\odot$ and $M_\star = 0.91 \pm 0.06 M_\odot$. We used these values to place Gaussian priors, by means of Bayesian penalties on $\chi^2$, at each MCMC step.

It was not necessary to add any jitter to the RVs of WASP-45.

### 4.3 The imposition of circular orbits

For each system, the best-fitting eccentricity is small and consistent with zero (Table 5). We used the $F$-test approach of Lucy & Sweeney (1971) to calculate the probability, $P_{\text{LS}}$, that the improvement in the fit that results from fitting for an eccentric orbit could have arisen by chance if the underlying orbit were circular. For each system, we found $P_{\text{LS}}$ to be much higher (Table 5) than the threshold of 0.05 suggested by Lucy & Sweeney (1971), below which they consider the detection of a non-zero eccentricity to be significant. In the absence of conclusive evidence to the contrary, we assumed the orbit of each planet to be circular in producing the adopted solutions that we present. This issue is dealt with at greater length in the discussion.

### 4.4 Results

The median values and 1σ uncertainties of the system parameters derived from the MCMC model fits are presented in Table 6. The corresponding transit models are superimposed on the transit photometry in Figs 1–3. The corresponding orbit models are superimposed on the RVs in Figs 4–6, in which we also show the RV residuals as a function of time. From the residual plots one can evaluate both the level to which stellar activity may have affected the RVs and the evidence for a third body. The RVs of each planet-hosting star, obtained over the course of 100 days, show no evidence for motion induced by a third body. The residuals of WASP-46 show greater scatter ($\chi^2 = 19.2$ for WASP-46 compared to 10.9 for WASP-44 and 7.4 for WASP-45), which is probably due to the star being active (see Sections 3 and 5).

We also performed MCMCs fitting an eccentric model to the RVs so as to illustrate the impact on those parameters that are liable to be
5 ROTATIONAL MODULATION

We analysed the WASP light curves of each star to determine whether they show periodic modulation due to the combination of magnetic activity and stellar rotation. We used the sine-wave fitting method described in Maxted et al. (2011) to calculate periodograms such as those shown in the upper panels of Fig. 8. These are calculated over 4096 uniformly spaced frequencies from 0 to 1.5 cycles d$^{-1}$. The false alarm probability levels shown in these figures are calculated using a bootstrap Monte Carlo method also described in Maxted et al. (2011). Variability due to star spots is not expected to be coherent on long time-scales as a consequence of the finite lifetime of star spots and differential rotation in the photosphere so we analysed each season of data separately.

We found no evidence of rotational modulation in any of the WASP-44 or WASP-45 light curves.

We applied the sine-wave fitting method to the WASP-46 light curves from each of the three seasons to produce the periodograms in the upper panels of Fig. 8. The peaks in the periodograms for the first two seasons of data are highly significant and imply periods of 16.55 ± 0.10 and 14.92 ± 0.07 d. We used a bootstrap Monte Carlo method to estimate the errors on these periods. The periodogram for the third season of data shows peaks corresponding to a period of 8.08 d. Our bootstrap Monte Carlo method fails to provide a reliable error estimate for this less significant peak. The amplitudes of the variations estimated from the sine-wave fits are in the range of 3–5 mmag (Fig. 8, lower panels). We also calculated periodograms of two stars with similar magnitudes and colours to WASP-46 observed simultaneously with the same camera. Neither of these stars showed significant periodic modulation in the same frequency interval with the exception of one data season for one star that showed significant power close to 1 cycle d$^{-1}$, the source of which is likely to be diurnal.

### Table 5. The limits placed on orbital eccentricity and the impact of fitting for it.

| Parameter (unit) | WASP-44 | WASP-45 | WASP-46 |
|------------------|---------|---------|---------|
| $\rho$ | 10.5 | 6.3 | 18.1 |
| $e$ | 0.036$^{+0.054}_{-0.025}$ | 0.023$^{+0.027}_{-0.016}$ | 0.018$^{+0.021}_{-0.013}$ |

| $R_{pl}(R_{Jup})$ | 1.00$^{+0.14}_{-0.13}$ | 1.17$^{+0.28}_{-0.28}$ | 1.327$^{+0.058}_{-0.058}$ |
| $\rho_{pl}(\rho_{Jup})$ | 0.69$^{+0.37}_{-0.20}$ | 0.64$^{+0.30}_{-0.30}$ | 0.90$^{+0.12}_{-0.12}$ |

This table demonstrates the effects of fitting for orbital eccentricity and is to be compared with Table 6, which presents our adopted solutions.
Our interpretation of these results is that the WASP light curve of WASP-46 does show periodic modulation due to the rotation of the star with a period of $16 \pm 1$ d. The period of 8.08 days derived from the third season of data can be explained by the distribution of star spots during this season resulting in a light curve with two minima per cycle. Similarly, the poorly defined peak in the periodogram for the second season of data may be due to the appearance and disappearance of star spot groups during the observing season.

Using the rotational-modulation period of $16 \pm 1$ d and the stellar radius from Table 6, we calculate the stellar rotation velocity $v$ to be $2.9 \pm 0.2$ km s$^{-1}$. That this value is higher than the value of $v \sin I$ ($1.9 \pm 1.2$ km s$^{-1}$) determined from spectral line profiles (Section 3) suggests that the stellar spin axis is inclined by $I = 41^\circ \pm 40^\circ$ with respect to the sky plane. This should be appreciated when assessing whether a measurement of WASP-46b’s Rossiter–McLaughlin effect is indicative of an aligned or a misaligned orbit (e.g. Schlaufman 2010). Usually only the sky-projected angle between the planetary orbit and stellar spin axis can be determined, but with a measurement of $I$ the true angle can be determined. Our measurement of $I$ is imprecise and would be improved by a more precise determination of spectroscopic $v \sin I$.

6 DISCUSSION

WASP-44b is a 0.89-$M_{\text{Jup}}$ planet in a 2.42-d orbit around a solar metallicity ([Fe/H] = 0.06 ± 0.10) G8V star. The star is observable from both hemispheres and seems to be inactive as it shows no signs of rotational modulation or Ca II H+K emission.

WASP-45b is a Jupiter-mass planet that partially transits its metal-rich ([Fe/H] = 0.36 ± 0.12) K2V host star every 3.13 d. The (near-)grazing nature of the transits led us to impose a prior on the density of the host star so that the derived stellar and planetary radii are physical. The star may be active as weak Ca II H+K emission is seen in its spectra, though no rotational modulation is evident in the light curves.

WASP-46b is a 2.10-$M_{\text{Jup}}$ planet in a 1.43-d orbit around a metal-poor ([Fe/H] = −0.37 ± 0.13) G6V star. We found the star to be active as weak Ca II H+K emission is present in its spectra and a clear 16-day rotational-modulation signature is evident in the WASP light curves. The slower rotation rate suggested by spectroscopic $v \sin I$ indicates that the stellar spin axis is inclined relative to the sky plane ($I = 41^\circ \pm 40^\circ$). By observing WASP-46b’s Rossiter–McLaughlin effect (e.g. Simpson et al. 2011), which is predicted to have an amplitude of $18$ m s$^{-1}$, we could thus measure the true angle between the stellar spin and the planetary orbit axes, rather than just the sky-projected angle. The large size of the planet, the high stellar insolation and the relative lateness of the host star make WASP-46b a good target for infrared occultation photometry (e.g. Anderson et al. 2011b).

The upper limits placed on the lithium abundances suggest that each star is at least a few Gyr old (Table 3; Sestito & Randich 2005), which is in contrast with the gyrochronological ages of $\sim 0.9$–1.4 Gyr.

6.1 Fit for eccentricity or impose a circular orbit

To obtain accurate stellar densities and the derivative stellar and planetary radii, we require not only high-quality transit light curves, but also accurate determinations of the orbital eccentricities. Measurements of these parameters inform intense theoretical efforts concerning tidal circularization and heating, bulk planetary composition and the observed systematic errors in planetary and stellar radii. For those planets with poorly constrained eccentricity, further RV and occultation-timing measurements are necessary. However, these will be performed slowly and perhaps only for a fraction of systems. As such, we should make every effort to avoid introducing biases into the sample that we have to work with.
Around half of all known transiting planets (i.e. those confirmed by a dynamical mass determination) are hot Jupiters ($P \leq 4$ d and $M_{pl} \approx 0.5$–$2 M_{Jup}$) and Pont et al. (2011) find no evidence for an eccentric orbit among these. Further, tidal theory predicts that the time-scale of tidal circularization is a sharp function of semimajor axis and planet radius, and a weaker function of planetary and stellar masses (Goldreich & Soter 1966). That is, low-mass, bloated planets in short orbits around high-mass stars are expected to circularize quickest. So, there is a theoretical basis and an empirical basis for expecting a newly discovered hot Jupiter to be in a circular orbit.

When a hot Jupiter is first announced the RV data often poorly constrain eccentricity and occultation observations are almost never available. In those circumstances, some authors have opted to impose a circular orbit (e.g. Anderson et al. 2011a; Faedi et al. 2011a), as is theoretically and empirically reasonable, though doing so does artificially reduce the uncertainties on the system parameters. Other authors have opted to fit for an eccentric orbit (e.g. Hellier et al. 2010; Bakos et al. 2011) so as to obtain more conservative error bars. Fitting an eccentric orbit model to RV measurements of a (near-)circular orbit will always result in a non-zero value of $e$ (e.g. Laughlin et al. 2005), and this can affect the derived stellar and planetary parameters. As compared to the circular solution, the eccentric solution will typically change the planet’s speed during transit and, as the transit duration is fixed by measurement, a change in speed necessitates a change in distance travelled during transit, i.e. the derived stellar radius. In turn, as the ratio of planetary-to-stellar radii is fixed by the measured transit depth, then the derived planet radius is changed.

Being aware of these issues, some authors have opted to present both a circular solution, which is most likely, and an eccentric solution, which gives a reliable account of the uncertainties in the data (e.g. Anderson et al. 2010). One issue with this approach is that many authors tend to prefer to work with a single solution and so will adopt the one they favour regardless. Another approach is to present the best-fitting parameter values from a circular fit and the error bars from an eccentric fit (e.g. Enoch et al. 2011; Maxted et al. 2011). Thus, the most likely solution is presented with conservative error bars, but care must be taken to calculate the 1σ confidence intervals in the posterior probability distributions about the best-fitting circular values.

As the best-fitting eccentricity values for the three systems presented in this paper are small ($e = 0.02$–$0.04$), the differences between the best-fitting parameter values from circular and eccentric solutions are small (compare Tables 5 and 6). However, eccentricity is often poorly determined in a discovery paper and the choice to fit for eccentricity then has a greater impact. An illustrative example is the case of WASP-17b. In the discovery paper (Anderson et al. 2010), we presented three solutions, including one with an imposed circular orbit which gave $R_{pl} = 1.97 \pm 0.10 R_{Jup}$, and another, which we adopted as our preferred solution, in which we fit for an eccentric orbit that gave $R_{pl} = 1.74^{+0.26}_{-0.23} R_{Jup}$ and $e = 0.129^{+0.106}_{-0.068}$. We had initially favoured the circular solution as theory suggested this as the most likely and the additional two free parameters of an eccentric orbit did not significantly improve the fit. However, we adopted the eccentric solution due to its more conservative error bars. We had been able to place only a weak constraint on eccentricity as the low mass of the planet (0.49 $M_{Jup}$) and the high effective surface temperature of the star (6650 K) caused our measurement of the reflex motion of the star to be quite low S/N. This situation improved when we observed two occultations of WASP-17b, which we used to show the orbit of WASP-17b to be very slightly eccentric ($e \approx 0.0055$; Anderson et al. 2011b) and the planet radius to be $1.991 \pm 0.081 R_{Jup}$. As such, the circular solution that we presented in the discovery paper was closest to describing the system and we would have done better to have adopted that.

By the time we had shown the orbit of WASP-17b to be near-circular, a number of papers had, at least in part, based their models, results or conclusions on the values of one or both of $e$ and $R_{pl}$ of the discovery paper’s adopted solution (e.g. Hansen 2010; Schlaufman 2010; Cowan & Agol 2011; Ehrenreich & Désert 2011). Though it is true that our updated solution was not excluded, not even at the 1σ level, some of those studies had only considered WASP-17 due to its apparent significant eccentricity, and other such works were sure to follow. For example, the possibility that tidal dissipation could have inflated WASP-17b would probably have been tested as was done by Ibugi et al. (2011) for other systems. Before we showed the planet to be even more bloated than first suggested and placed a much tighter constraint on eccentricity, tidal heating had seemed a much more likely explanation for the anomalously large size of WASP-17b.

A more recent example, which is similar to the case of WASP-17 and became available after submission of this paper, is that of HAT-P-32 and HAT-P-33 (Hartman et al. 2011). In both systems, the S/N of the stellar radial motion, as induced by the orbiting planet, is low and eccentricity is poorly constrained. In an early draft (arXiv:1106.1212v1), eccentric solutions were presented alongside circular solutions such that the reader could choose which to adopt. The derived planetary radii differ significantly between the eccentric and circular solutions, with 1.8 $R_{Jup}$ versus 2.0 $R_{Jup}$ for HAT-P-32b and 1.7 $R_{Jup}$ versus 1.8 $R_{Jup}$ for HAT-P-33b. In the published version of the paper, Hartman et al. (2011) instead suggest adoption of the circular solutions, but caution that several eccentric short-period planets are known. The three example exoplanets given, XO-3b, WASP-14b and HAT-P-21b, are each much more massive and smaller than HAT-P-32b and HAT-P-33b, and are in similar or longer orbits. Each effect acts to increase the tidal circularization time-scale. Thus, it is little wonder that these planets are in eccentric orbits, but it would be surprising if HAT-P-32b or HAT-P-33b were.

Unless there is clear evidence for an eccentric orbit, we recommend imposing a circular orbit when deriving the parameters of a hot-Jupiter system. This will avoid creep in the literature of parameter values as further RV and occultation observations show discovery-paper eccentricities to be spurious. Though further measurements will show some planets to have a small, non-zero eccentricity, for the majority eccentricity will be constrained to ever smaller values consistent with zero.

ACKNOWLEDGMENTS

WASP-South is hosted by the South African Astronomical Observatory and SuperWASP-N is hosted by the Isaac Newton Group on La Palma. We are grateful for their ongoing support and assistance. Funding for WASP comes from consortium universities and from the UK’s Science and Technology Facilities Council. TRAPPIST is a project funded by the Belgian Fund for Scientific Research (Fond National de la Recherche Scientifique, FNRS) under the grant FRFC 2.5.594.09.F, with the participation of the Swiss National Science Foundation (SNF). MG and EJ are FNRS Research Associates.
