ABSTRACT

Background: Rifampicin resistant tuberculosis (RR-TB) was frequently detected in Suriname after the introduction of Xpert MTB/RIF in 2012. Subsequent phenotypic drug-susceptibility testing (DST) was not conclusive at that moment, while RR-TB patients treated with first-line tuberculostatics had good treatment outcome. In our study, we analysed this interesting observation.

Methods: We collected demographic and clinical characteristics and treatment outcome of TB patients from May 2012-December 2018 and performed a univariate and multivariate analysis to assess possible associations with resistance to rifampicin. Secondly, we conducted whole genome sequencing on all available Mycobacterium tuberculosis isolates that had a rifampicin resistance in the Xpert MTB/RIF test and performed phenotypic DST on selected isolates.

Findings: RR-TB was detected in 59 (9.6%) patients confirmed by Xpert. These patients were treated with rifampicin-containing regimens in most (88%) of the cases. In all 32 samples examined, a D435Y mutation in the rpoB gene was identified; only one isolate revealed an additional isoniazid mutation. Phenotypic DST indicated low-level rifampicin resistance. In multivariate analysis, the Creole ethnicity was a factor associated with rifampicin resistance (aOR 3.5; 95%CI 1.9–6.4). The treatment success rate for patients with RR-TB (78.0%) was comparable to the treatment outcome in non-RR-TB patients 77.8%.

Interpretation: This study confirms a low-level rifampicin mono-resistance in TB patients of Suriname. These patients could benefit from a first-line regimen with high dose rifampicin (or rifabutin), rather than from the lengthy treatment regimens for rifampicin-resistant and multi-drug resistant TB, a concept of stratified medicine also advocated for the treatment of TB.

Funding: None.

1. Introduction

Globally, an estimated 10 million people developed tuberculosis (TB) in 2018; half a million of them had rifampicin-resistant (RR) TB [1], of which 78% had also confirmed resistance to isoniazid (INH), and were hence classified as multidrug-resistant (MDR) TB.

The last decade brought large improvements in the diagnosis and treatment of RR/MDR-TB.[2] For instance, rifampicin resistance can now be diagnosed with rapid molecular tests and new effective second-line drugs as bedaquiline and linezolid, are now included in injection-
TB, were not actively followed up after treatment completion. Caribbean TB guidelines [5], with a standard regimen of isoniazid, National Treatment Guidelines, which had been based on the 2010 was microscopically negative after 6 months treatment. A positive smear medically or culture positive after 5 months treatment and cure if the smear picin were treated for 12 months. Patients, including those with RR-TB treatment or RR-TB. Patients treated with a regimen without rifamycinic resistance in these strains. [4] In 2018, 12.4% of confirmed cases in Suriname had RR-TB, which is the highest proportion in the WHO Region of the Americas. [1]

This study aims to identify characteristics of the RR-TB patients in Suriname, understand the resistance pattern found, search for similar strains in the Netherlands, a country with strong historical ties to Suriname, and identify possible implications for treatment recommendations.

2. Methods

2.1. Patients

In Suriname, TB patients are mandatory reported to the National Tuberculosis Program (NTP), which maintains an electronic national TB register. In our study, we included TB patients who were notified between May 2012 and December 2018. Patients were treated according to National Treatment Guidelines, which had been based on the 2010 Caribbean TB guidelines [5], with a standard regimen of isoniazid, rifampicin, ethambutol and pyrazinamide. Streptomycin and/or ciprofloxacin were added to the regimen in some patients who had previous TB treatment or RR-TB. Patients treated with a regimen without rifampicin were treated for 12–18 months. Patients, including those with RR-RB, were not actively followed up after treatment completion.

The following data were obtained from the register: sex, age, ethnicity, site of disease, smear results, Xpert results, drug-resistance, case type (new or previously treated), current TB treatment regimen, co-morbidities (HIV, diabetes mellitus), illicit drug use (marihuana or hard drugs) and treatment outcome. Treatment outcomes (including RR-TB) were based on the definitions and reporting framework for drug-sensitive TB [6], e.g. failure was defined if the sputum was microscopically or culture positive after 5 months treatment and cure if the smear was microscopically negative after 6 months treatment. A positive smear was graded as previously described. [7]

We compared demographic and clinical characteristics of Xpert-confirmed rifampicin-sensitive and rifampicin-resistant TB patients. Data were analysed with SPSS version 24 (SPSS, Inc., Chicago, IL, USA), including a univariate analysis to estimate the Odds Ratio (OR) and 95% Confidence Intervals (95%CI) and a multivariate regression analysis including those variables that attained a P value < 0.25 in the univariate analysis.

2.2. Mycobacterium tuberculosis isolates Suriname

In Suriname, samples of all TB patients are sent to the Central Laboratory, which accommodates the national TB reference laboratory, and performs culture (Löwenstein Jensen) and strain identification (SD BIOLINE TB Ag MPT64). Cultured M. tuberculosis isolates are stored at minus 80°C.

In 2018, 32 stored Xpert rifampicin-resistant Mycobacterium tuberculosis isolates were re-cultured and sent to the National Tuberculosis Reference Laboratory of the National Institute for Public Health and the Environment (RIVM) in the Netherlands for further analysis. These isolates were from patients diagnosed in 2012 (n = 4), 2013 (n = 4), 2014 (n = 10), 2015 (n = 8), 2017 (n = 3) and 2018 (the first three RR-TB patients in that year). Rifampicin-resistant M. tuberculosis isolates from 2016 were not available for analysis. At the RIVM, whole genome sequencing (WGS) was applied to detect mutations associated with resistance and to determine the genetic distance between the isolates, as a proxy for epidemiological links between cases. Additionally, reverse line blot assays (GenoType MTBDRplus® Hain Lifesciences, Nehren, Germany) and phenotypic DST were performed on selected isolates.

2.3. Similar isolates in the Netherlands

We searched the Dutch TB laboratory database at the RIVM for isolates with the same mutation found in Suriname, and obtained data from the Dutch National TB Register of patients infected with M. tuberculosis isolates with this mutation. Isolates that were possibly identical with the strain found in Suriname were subjected to WGS.

2.4. Ethical consideration

Ethical approval for this study was obtained from the Human Scientific Research Ethic Committee of the Ministry of Health of Suriname. The Dutch National TB Registration Committee approved the use of the data from the Netherlands for this study.

3. Results

3.1. Patients

Between May 2012 and December 2018, a total of 978 TB patients were notified to the NTP in Suriname. The male–female ratio was 2.5 (696 male patients; 71%) with a median age of 42 years (interquartile range [IQR] 29–53). Patients’ ethnicity was mostly Creole (32%), followed by Maroon (16%), Hindustani (15%) or mixed ethnicity (16%). Eighty-six percent (n = 838) of the patients had pulmonary TB; 599 had a smear positive sputum with microscopy (71% of pulmonary TB patients). Xpert was positive in 64% (n = 623) of the patients; whilst negative or not done in the remaining 36% (n = 355) of patients. Rifampicin resistance was determined in 59 (9.5%) of Xpert-positive patients (Table 1). Nine percent of patients (n = 91) were previously treated for TB. HIV status was known in 939 patients (96%) and HIV co-infection was present in 23% (n = 218) of tested patients. Diabetes mellitus was prevalent in 13% of the patients (n = 123) and illicit drug use was reported in 24% (n = 239) of the patients.

In univariate analysis, RR-TB patients were significantly more often in the age group 45–60 years (reference 15–24 years), had the Creole ethnicity (aOR 3.5) (Table 2). HIV and illicit drug use were confounding factors related to Creole ethnicity: 32% (64/198) of all Xpert-positive Creole TB patients were HIV co-infected and 42% (84/
In total, 12 RR-TB patients were previously treated for TB (one person was treated for TB two times and another person three times). Of these patients, five had a TB diagnosis before 2012 with an unknown resistance pattern, and in one patient DST was not done in the previous episode.

*Creole: descendant of African slaves; Maroon: descendant of escaped African slaves; Hindustani: descendant of contract laborers from what was then British India; Javanese: descendant of contract laborers predominantly from Java, Indonesia [33].

198) had documented illicit drug use versus respectively 12% and 23% of patients with other ethnicities.

Treatment outcome was successful (cured/completed) in 74.6% of all TB patients, in 77.8% of patients with Xpert rifampicin-sensitive TB and in 78.0% of patients with Xpert diagnosed RR-TB (Table 3). Second-line drugs (ciprofloxacin (n = 15), streptomycin (n = 2), or both ciprofloxacin and streptomycin (n = 20)) were added to the standard first-line treatment regimen in 37 patients; 21 of these patients had rifampicin-sensitive TB (4% of all rifampicin-sensitive TB patients) and 16 had RR-TB (27% of all RR-TB patients). Fifty-two (88%) RR-TB patients were treated with rifampicin-containing first-line regimens (11 out 52 were also treated ciprofloxacin and/or streptomycin), five (8%) patients were treated with the first-line drug regimen without rifampicin but to which was added ciprofloxacin and/or streptomycin, and two (3%) patients did not start treatment.

In total, 12 RR-TB patients were previously treated for TB (one person was treated for TB two times and another person three times) (Table 4). Three of these patients restarted treatment after discontinuing the treatment in the first episode (two had RR-TB in the first episode, the other one had a diagnosis before 2012) and nine completed treatment in the first episode (two diagnosed with RR-TB before, one with rifampicin-sensitive TB, five had a TB diagnosis before 2012 with an unknown resistance pattern, and in one patient DST was not done in the previous episode).

3.2. Whole genome sequencing (WGS) and additional laboratory tests

WGS revealed a D435Y mutation in the rpoB gene in all 32 rifampicin-resistant *M. tuberculosis* isolates. One isolate had an additional resistance mutation in the inhA gene S94A, but not in the more common inhA promoter gene region, and by definition labelled as MDR. None of the remaining 31 isolates had additional first-line drug resistance-associated mutations in the katG, inhA, fabG1, ahpC, embA, embB, pncA or rpsA genes. The 32 isolates were all linked together by WGS in one genetic cluster with ≤ 12 single nucleotide polymorphisms (SNPs) difference to each other.

The GenoType MTBDRplus analysis of 14 isolates (from 2015 to 2018) showed loss of hybridization of wild type probes 3 and 4, and no hybridization of the known and most frequently reacting mutation of rifampicin of 1–5 mg/L, known as low level resistance (cut-off is 1 mg/L) and showed susceptibility to rifabutin for the three isolates tested (all patients diagnosed in 2018). These three isolates were also tested in the MGIT and were found susceptible to rifampicin.

3.3. D435Y isolates and patients in the Netherlands

The Dutch national TB laboratory database contained 15
10 non-Suriname-born patients were resistant to isoniazid and 8 out of Suriname (Table 5). The isolates were from patients born in Europe (n = 3) and Asia (n = 1). The isolates from the 10 non-Suriname-born patients were resistant to isoniazid and 8 out of

**Table 3**

Abbreviations: TB = tuberculosis

41 rifampicin-resistant tuberculosis (RR-TB) patients were treated with first-line drugs including standard dose rifampicin; 36 (87.8%) had a successful treatment outcome (median days treatment: 198; interquartile range [IQR] 187–222). 11 RR-TB patients were treated with first-line drugs including standard dose rifampicin, and in addition with ciprofloxacin (n = 4), streptomycin (n = 1) or ciprofloxacin and streptomycin (n = 6); 6 (55%) had a successful treatment outcome (median days treatment: 289; IQR 280–304). Five RR-TB patients were treated with first-line drugs without rifampicin, and in addition with ciprofloxacin (n = 2) or ciprofloxacin and streptomycin (n = 3); 4 (80%) had a successful treatment outcome (median days treatment: 381; IQR 362–447). Two RR-TB patients did not start treatment: one died before treatment and one was not evaluated.

Patients with rifampicin-resistant tuberculosis in Suriname who were previously treated for tuberculosis, May 2012 - December 2018.

4. Discussion

Our study shows that rifampicin-resistant TB in Suriname is caused by a *M. tuberculosis* isolate with a D435Y mutation in the *rpoB* gene, known to be associated with a low-level resistance for rifampicin.[9–12]

Only one patient had also an uncommon mutation coding for isoniazid resistance and hence had MDR-TB; all other RR-TB patients had rifampicin mono-resistant isolates. RR-TB patients were mainly treated with rifampicin-containing regimens. Treatment outcome was similar in patients with rifampicin-sensitive and RR-TB, with a successful treatment completion rate of 78% in both groups. Patients were not actively followed up after treatment completion and only identified with recurrent TB if they presented with symptoms and were diagnosed. Patients with isolates harbouring the D435Y mutation were also identified in the Netherlands, but only the patients born in Suriname had an infection with a rifampicin mono-resistant strain. These patients had been treated either as rifampicin-sensitive TB, or with first-line regimens including rifabutin.

Rifampicin resistance in *M. tuberculosis* is mostly caused by an undisputed mutation in the *rpoB* gene, most commonly the S450L mutation. The D435Y mutation described in our study is a mutation with disputed drug-resistance and characterised by a substitution of the amino acid asparagine (Asp/D) by tyrosine (Tyr/Y) in codon 516.[13] In the previous classification with *E. coli* codon numbering, this mutation was known as D516Y or GAC516TAC and renamed with the H37rν numbering to D435Y. Studies investigating the accuracy of current laboratory tests to identify resistance in D435Y mutation isolates concluded that low level rifampicin resistance is often missed in the single point concentration MGIT-DST, while it is identified by MIC methods like Middlebrook 7H10 and Löwenstein-Jensen and by molecular test such as Xpert and MTBDRplus.[9–11,14] Other studies concluded that the rifampicin resistance is often borderline or low level. [12,15–19] Almost all studies concluded that isolates with a D435Y mutation are susceptible to rifabutin.[10,15–17,20]

The Suriname NTP had difficulties in the interpretation of the rifampicin resistance detected by the Xpert test. In 2012, six Xpert rifampicin-resistant *M. tuberculosis* isolates were transported to an international laboratory, where MGIT-DST and 7H10 Middlebrook MIC method revealed susceptibility to rifampicin in all isolates. In 2016, the supranational reference laboratory of Massachusetts re-analysed these isolates using an agar proportion method and found rifampicin resistance in four of the six isolates. Furthermore, it performed PCRamplified direct DNA sequencing of the *rpoB* gene on these six isolates and on 10 lysates of Xpert rifampicin-resistant *M. tuberculosis* isolates from 2014, revealing the D435Y mutation in 14 of the 16 samples.[4]

WHO’s treatment advise on rifampicin mono-resistant TB has changed over time. In the first guidelines on drug-resistant TB, a 12–18 months regimen with isoniazid, ethambutol and a fluoroquinolone, and

*M. tuberculosis* isolates with the same D435Y mutation found in Suriname (Table 5). The isolates were from patients born in Europe (n = 6), Suriname (n = 5), Africa (n = 3) and Asia (n = 1). The isolates from the 10 non-Suriname-born patients were resistant to isoniazid and 8 out of 10 susceptible to rifabutin; patients were treated accordingly (Table 5). The isolates from the 5 Suriname-born patients were all susceptible to isoniazid, rifampicin-susceptible in two cases (both tested by MGIT-DST) and low-level rifampicin-resistant in three cases (one patient with recurrent TB was counted twice; all these isolates were tested by Middlebrook 7H110). The two patients with rifampicin-sensitive TB completed standard first-line treatment, including standard dose rifampicin. One RR-TB patient was treated for 6 months with a first-line regimen, containing rifabutin instead of rifampicin, to which the strain was susceptible. The patient diagnosed twice with RR-TB first completed 12 months treatment with isoniazid, ethambutol, moxifloxacin and 2 months pyrazinamide, but developed RR-TB again after ten years. This second time, he was treated for 6 months with the first-line drug regimen, with rifabutin, to which the strain was susceptible, replacing rifampicin. Genotypically, all five *M. tuberculosis* isolates of the Suriname-born patients in the Netherlands clustered in the WGS with those of the 32 patients diagnosed in Suriname.
treatment regimens with isoniazid and rifampicin can still be effective. rifampicin resistance and susceptibility for isoniazid, suggests that M. tuberculosis that contains to our knowledge the largest set of patients infected with streptomycin (\textit{Category 2 regimen}) for patients with relapse or return after loss to follow-up. In 2011, WHO published an update stating that the detection of rifampicin resistance by Xpert test usually suffices to prescribe second-line TB regimen [22], but also cautioned for situations in which the Xpert test has a low predictive value and advised that results need to be confirmed by phenotypic DST or line probe assay. The update also noted that a potential harm from placing all rifampicin-resistant patients on an MDR-TB regimen, was the exclusion of isoniazid from their treatment, thus depriving them of a safe and useful bactericidal drug. [22] A systematic review in 2016 identified only three studies reporting treatment outcomes for patients with RR-TB, preventing a meta-analysis. [23] Since 2016, WHO guidelines on drug-resistant TB recommend similar treatment regimens for patients with RR-TB and MDR-TB. [3,24] The guideline for treatment of TB and RR/MDR-TB in Suriname was updated following these latest recommendations of the WHO, and does not include ciprofloxacin and streptomycin anymore because of limited evidence of their effectiveness and sterilizing activity.

The clinical relevance of disputed mutations with low-level rifampicin resistance has been an issue of debate. One study indicated that disputed mutations had the same poor clinical prognosis as the most frequent undisputed mutations. [25] Williamson et al. suggested to conduct a multi-centre retrospective study to correlate the different types of \textit{rpoB} mutations with clinical outcomes. [18] They stated that the retrospective nature of such a study would actually become a methodological strength, as it would allow data on treatment outcome to be obtained, and thus allow the clinical relevance of mutations to be assessed. [18] We consider our observational study to be such a study, that contains to our knowledge the largest set of patients infected with \textit{M. tuberculosis} strains carrying the D435Y mutation. Our observation of good treatment results of patients with this peculiar type of low-level rifampicin resistance and susceptibility for isoniazid, suggests that treatment regimens with isoniazid and rifampicin can still be effective. The relatively high number of RR-TB cases with previous TB treatment is a concern and suggests that a sterilizing effect was not achieved. However, one-quarter of these patients did not complete the previous treatment which obviously contributed to relapse, while reinfection is also possible in an environment with ongoing transmission.

Several authors have proposed alternative treatment options for patients infected with a low-level rifampicin resistance, e.g. a higher dose of rifampicin or replacing rifampicin by rifabutin. [10,16,18,20,26] The currently recommended dose of rifampicin has been challenged over the last years. [27,28] Dosage studies indicate that 35 mg/kg rifampicin instead of 10 mg/kg is well tolerated and more effective than the standard dose. [29,30] These authors recommend high dose rifampicin for patients with TB meningitis, co-infection with HIV, diabetes mellitus and serious ill TB patients, since plasma concentrations of rifampicin are often too low. Our hypothesis is that patients with low-level rifampicin mono-resistant TB could benefit more from a first-line regimen, including isoniazid and high dose rifampicin (or rifabutin), rather than from a lengthy regimen for RR/MDR-TB treatment or the standard TB treatment. We have developed a study to treat these patients accordingly in Suriname and a protocol has been developed and cleared by the Human Scientific Research Ethic Committee, and includes informed consent of the patient for treatment with high-dose rifampicin (30 mg/kg); timely WGS testing of all RR-isolates; measuring of rifampicin blood levels; close supervision of treatment, including monitoring of side effects; case discussion in a Concilium; and a minimal follow-up of one year after treatment.

Our study also revealed several other issues, some beyond the scope of this study. All examined isolates of RR-TB patients, both found in Suriname and the Netherlands, belonged by WGS genetically to one large molecular transatlantic cluster. Transmission of the rifampicin-resistant strain is likely to be ongoing in Suriname, and possibly also in the Netherlands. Second, the observed TB/HIV co-infection rate (23%) is one of the highest in the WHO Region of the Americas [1]. More TB/HIV collaborative efforts are needed to control TB and move towards TB elimination in Suriname. RR-TB was more often detected in Creole people, which is also the ethnic group with a very high TB incidence, HIV co-infection rates and illicit drug use. Our data show a high TB case fatality of 14%, which has been associated with higher age and HIV co-infection. [31]

Our study had several strengths and limitations. We made use of a detailed electronic database and advanced molecular tests were applied on a subset of rifampicin-resistant \textit{M. tuberculosis} isolates, although not all rifampicin-resistant isolates were available for additional typing. The 100% concordance of rifampicin resistance found by Xpert in Suriname and by WGS in the Netherlands, confirmed that these patients actually had RR-TB. The major limitation of our study is that RR-TB patients were not actively followed up for recurrent TB after treatment completion. We will address this issue in the planned prospective study. Our analysis did not include rifampicin-susceptible isolates. Recently, we analysed another 118 lysates, including 18 rifampicin-resistant strains of patients diagnosed in 2018–2020. All rifampicin-resistant isolates had the D435Y mutation; none of the other strains carried mutations in the \textit{katG} or in\textit{hba} genes or had other first-line drug resistance.

\( a \) Patients 4, 6, 10, 12 and 15 had clustering of \textit{M. tuberculosis} isolates in Whole Genome Sequencing (<12 single nucleotide polymorphism difference).

\( b \) The \textit{M. tuberculosis} isolate had two mutations in the \textit{rasp} gene, i.e. D435SY and S450L.

- rifampicin resistance has been an issue of debate. One study indicated that disputed mutations with low-level rifampicin resistance are likely to be ongoing in Suriname, and possibly also in the Netherlands. Second, the observed TB/HIV co-infection rate (23%) is one of the highest in the WHO Region of the Americas [1]. More TB/HIV collaborative efforts are needed to control TB and move towards TB elimination in Suriname. RR-TB was more often detected in Creole people, which is also the ethnic group with a very high TB incidence, HIV co-infection rates and illicit drug use. Our data show a high TB case fatality of 14%, which has been associated with higher age and HIV co-infection. [31]
associated mutations.

The findings of our study provide clarity to the rifampicin resistance situation in Suriname and possible implications for tailored treatment regimens. Our study shows that an epidemic of RR-TB was driven by a mutation of which the clinical significance is disputed. All but one strains examined revealed low-level rifampicin resistance and isoniazid susceptibility. Treatment results with rifampicin-containing regimens were unexpectedly good. Further research is needed to study alternative treatment options for these patients, such as regimens with high dose rifampicin for these specific groups of patients, with systematic follow-up after treatment completion. We state that one size does not fit all for the treatment of RR/MDR-TB, i.e. some people need XL (extra-large) and others XS (extra-small) treatment regimens, depending on the causative strain. Technological advances make it increasingly possible to tailor treatment to the patient and their bacteria. Furthermore, collaborative networks of professionals and countries with different resources can work together to provide the necessary scientific evidence for effective XL or XS RR/MDR-TB treatment regimens. In the end, we want to provide each patient the right treatment, not too much and not too little, a stratified of medicine also advocated for the treatment of TB.
