By constructing an Ising analogue of compact-star matter at sub-saturation density we explored the effect of Coulomb frustration on the nuclear liquid-gas phase transition. Our conclusions is twofold. First, the range of temperatures where inhomogeneous phases form expands with increasing Coulomb-field strength. Second, within the approximation of uniform electron distribution, the limiting point upon which the phase-coexistence region ends does not exhibit any critical behaviour. Possible astrophysics consequences and thermodynamical connections are discussed.

In absence of Coulomb interactions, the aspect of warm nuclear matter below its saturation density is a dense phase immersed in a low-density gas. The Coulomb repulsion strongly affects this liquid-gas phase transition by forbidding the condensation in macroscopic drops. This phenomenon, originally described in condensed-matter studies with the name of “frustration”, denotes all systems where no states exist where all interaction energies are simultaneously minimised: they range from magnets on specific lattices to liquid crystals, from spin glasses to protein folding.

Nuclear matter in the density range of the liquid-gas phase transition can be produced either in the expansion and disassembling of nuclei involved in violent ion collisions, or in the core of supernovae explosions, as well as in inner neutron-star crusts. It is known since the seventies\textsuperscript{[1]} that the clustered solid configurations in the inner crust of a neutron star give rise to complex phases\textsuperscript{[2]}, which are often quoted as pasta phases because of their suggestive topologies. Recent molecular-dynamics simulations show that these structures may survive also at finite temperature\textsuperscript{[3]}. The fluctuations connected to pasta phases are expected to enhance matter opacity to neutrino scattering with important consequences on the supernova explosion and cooling dynamics\textsuperscript{[3,4]}. Such a coherent neutrino-matter scattering is not only expected at low temperature, but even more in the possible occurrence of a critical point in the post-bounce supernova explosion, with the associated phenomenon of critical opalescence\textsuperscript{[4,5]}. At variance with usual-matter properties, the expected increase in the static form factor was not observed in molecular-dynamics simulation of stellar matter at finite temperature\textsuperscript{[6]}. This might be an effect of the Coulomb interaction which also acts in finite nuclei. However, it should be observed that, differently from nuclei, star matter includes also electrons with the role of neutralising the net charge over macroscopic portions.

The motivation of the present work is to provide general insights about the phase-transition phenomenology of neutral systems with Coulombic interactions. We construct an Ising analogue of compact-star matter by adding long-range interactions and a background of electrons to a Lattice-Gas model. Such an approach allows to take into account charge-density fluctuations by exact calculations, and to compare stellar matter with respect to other physical systems subjected to frustration, like hot atomic nuclei\textsuperscript{[7,8]} and Coulomb-frustrated ferromagnets\textsuperscript{[9]}.

Let us consider a neutral system composed of charged particles occupying a cubic lattice of $V$ cells with occupation numbers $n_i = 0,1$ immersed in a uniform background of negative charge representing the incompressible degenerated gas of electrons\textsuperscript{[12]}. This leads to a charge $q_i = n_i - \bar{n}$ for each site $i$, where $\bar{n} = \sum_j n_j/V$ comes from the uniform background. The schematic Hamiltonian $\mathcal{H}_{N+C} = \mathcal{H}_N + \mathcal{H}_C$ reads

$$\mathcal{H}_N = \frac{\epsilon}{2} \sum_{i,j} V n_i n_j, \quad \mathcal{H}_C = \frac{\lambda c}{2} \sum_{i \neq j} \frac{q_i q_j}{r_{ij}},$$

where $\sum'$ extends over closest neighbours. The isospin degree of freedom is not explicitly accounted, to allow a delocalization of the charge over the lattice\textsuperscript{[10]}. The nuclear symmetry energy, here neglected, is known to change only quantitatively the phase diagram\textsuperscript{[11]}. The short-range (nuclear-like $\mathcal{H}_N$) and long-range (Coulomb-like $\mathcal{H}_C$) interactions are characterised by the coupling constants $\epsilon$ and $\lambda c$ respectively, so that $\lambda$ measures the strength of frustration. To mimic stellar matter the numerical values are set to $\epsilon = -5.5 MeV$ and $\lambda c = \alpha E N_0^{1/3} \rho_0^{2/3}$, where $\rho_0 = 0.17 fm^{-1}$ is the nuclear saturation density, and $x = 1/3$ is a typical proton fraction. $\mathcal{H}_C$ can be rewritten as $\mathcal{H}_C = \lambda c \sum_{i,j} V n_i n_j C_{ij}$, where $C_{ij} = r_{ij}^{-1} - \bar{r}^{-1}$ if $i \neq j$ and $C_{ii} = -\bar{r}^{-1}$ with $\bar{r}^{-1} = \sum_{j \neq 0} V \bar{r}_{0j}^{-1}$ and the distance $r_{ij}$ is imposed to be the shortest between $i$ and $j$ in the periodic space. To numerically accelerate thermodynamic convergence, the finite lattice is repeated in all three directions of space a

*member of the Institut Universitaire de France
large number $R$ of times, analogous to the Ewald summation technique. Each site $i$ has then $R$ replicas of itself, each one displaced from $i$ of a vector $mL$, where $m$ has integer components and $L = \sqrt[N]{V}$ is the cubic lattice length. This procedure is equivalent to a renormalisation of the long-range coupling $C_L$ [12].

In ref. [8] a complete thermodynamic study of frustration is dedicated to Ising ferromagnets, described by the Hamiltonian

$$H_{Fe} = \frac{\epsilon}{2} \sum_{i,j} s_i s_j + \frac{\lambda}{2} \sum_{i \neq j} s_i s_j |ij|,$$

(2)

where $s_i = n_i - 1/2$ is a spin variable. The two models are related by:

$$H_{Fe} = H_{N+C} + \frac{\lambda}{2} \sum_i M^2 + \mu_c M - \frac{3}{4} \epsilon V,$$

(3)

where $M = \sum_i s_i$ is the magnetisation. We deduce that, contrarily to the standard form of closest-neighbour interactions, the charged Lattice-Gas model, eq. (1), in the grand canonical ensemble cannot be mapped into an Ising-ferromagnet model, eq. (2), in an external magnetic field because of the term in $M^2$ in eq. (3). Since this term scales with $V^2$, a thermodynamic limit exists for $H_{Fe}$ only for vanishing magnetisation conversely to $H_{N+C}$ [12].

Since $M$, or the particle density $\rho = M/V + 1/2$, is an order parameter of the Ising model, to impose $M = 0$ as a strict constraint can modify the thermodynamics of the system [12]. Moreover, the presence of the non-linear term $M^2$ directly affects the curvature of the order parameter distribution and so modifies the phase properties.

Clarified these distinctions, henceforth we analyse the thermodynamics of the $H_{N+C}$ Hamiltonian.

The multi-canonical ensemble [8] is a specifically adapted statistical tool to deal with frustrated systems. The Hamiltonian components $H_N, H_C$ are treated as two independent observables associated to two Lagrange multipliers $\beta_n, \beta_C$, respectively. The multi-canonical partition sum reads

$$Z_{\beta_n,\beta_C}(N,V) = \int W(E_n, E_C, N, V) e^{-\beta_n E_n - \beta_C E_C} dE_n dE_C,$$

(4)

where $W(E_n, E_C, N, V)$ is the density of states with nuclear energy $E_n$, Coulomb energy $E_C$, and number of particles $N$. A generalized grand potential is defined by

$$Z_{\beta_n,\beta_C,\alpha}^G(V) = \int Z_{\beta_n,\beta_C}(N,V) e^{\beta_n \alpha N} dN.$$

(5)

When $\beta_C = \beta_n$ the ensemble coincides with the conventional grandcanonical form. When $\beta_C = 0$ the system reduces to the standard Ising model. Therefore, the multi-(grand)canonical ensemble allows to construct one single phase diagram both for neutral and charged matter by exploring the space $(\beta_n, \beta_C)$. It should be noticed that varying independently $\beta_n$ and $\beta_C$ is equivalent to changing the effective charge $e_{eff}^2 = \lambda \beta_C/\beta_n$.

The canonical phase diagram in the $(\beta_n, \beta_C)$ space can be accessed from the topological properties of the particle density distribution in the corresponding grand-canonical ensemble eq. (5) [10]. For a given value of $\beta_C$, Fig. 1a describes, as a function of the inverse temperature $\beta_n$, the grand-canonical density distribution calculated at the critical chemical potential $\mu = \mu_c$. This distribution is sampled from eq. (5) with a standard Metropolis technique [10]. At high $\beta_n$, the density distribution shows two peaks of the same height, which are associated to two coexisting phases [10]. These two phases join at the limiting temperature (point (4)) above which the distribution stops to be bimodal. From a series of similar calculations performed for different values of $\beta_C$, we could extract the evolution of the inverse limiting temperature as a function of $\beta_C$ as plotted in Fig. 1b. We observe an increase of the limiting temperature $\beta_n^{-1}$ for increasing strength of the Coulomb field (about 6% for a proton fraction $x = 1/3$).

It is important to notice that many other physical systems subjected to Coulomb frustration exhibit the opposite behaviour. This is notably the case of frustrated Ising ferromagnets, as well as of finite atomic nuclei. In such cases the Coulomb repulsion is known to reduce the limiting temperature in the astrophysical context [2,13,14]. However, a recent calculation of nuclear-pasta structure within the RMF model [12] indicated a widening of the density range connected to the mixed

![FIG. 1: (Color online) Metropolis calculations ($\mu = \mu_c$, $L = 10$): (A) The logarithmic cluster plot gives the density distributions for different values of $\beta_n$ and for $\beta_C = 0.83\alpha$, which is the inverse limiting temperature computed for $\beta_C = \beta_n$. The solid line indicates the ridge of the distribution, the dashed line the coexistence region of an Ising-like system ($\beta_C = 0$). The points (2) and (4) indicate the limiting temperatures for $\beta_C = 0$ and $\beta_C = \beta_n$. (B) Phase diagram in the multi-canonical ensemble giving the inverse limiting temperature $\beta_n$ as a function of $\beta_C$. The points (1) and (3) are used in Fig. 2.](Image)
phase region when the Coulomb field is included under the constraint of charge neutrality over the Wigner-Seitz cells. Our results are consistent with this finding, and suggest that this effect is model independent and should persist at finite temperature[13].

The analysis of the event distribution elucidates the physical origin of the increase of the limiting temperature. The left side of Fig. 2 shows the transition from subcritical to critical partitions for an uncharged system ($\beta_C = 0$). When the system is uncharged, the observable $E_C$ defined in eq. (1) does not represent a physical Coulomb energy, and measures the compactness of the system. Its contribution does not influence the partition probability since $\beta_C = 0$, and compact clustered partitions with high $E_C$ can be explored.

When the system is charged (right side of Fig. 2), $E_C$ enters in the partition distribution eq. (5) as the physical Coulomb energy. This energy is maximal in fragmented configurations at $\rho/\rho_0 \approx 0.5$, and minimal in pure-phase events, where the largely uniform proton-charge distribution is almost exactly compensated by the electron background. The pure-phase events are then increasingly favored with increasing charge. Thus, bimodal distributions are still found in the charged system (panel 3) at temperatures at which critical events dominate the uncharged system (panel 2). This is entirely due to the screening effect of the electrons, while in finite nuclei the highest Coulomb energy is associated to the homogeneous liquid-like partitions, leading to the opposite effect.

The question now arises as to whether the limiting points of the frustrated system are second-order critical points like in the uncharged system, or in the Coulombic RPM model describing phase separation in electrolytes [21]. Criticality arises from the divergence of the correlation length $\xi$. It describes the exponential decay of the correlation function $\sigma(r_{ij}) = \langle \delta n_i \delta n_j \rangle - \langle n_i \rangle \langle n_j \rangle$ according to the expression $\sigma(r) \propto e^{-r/\xi \cdot r^{-(d-2+n)/\eta}}$, where $D$ is the space dimension and $\eta$ is a critical exponent. Using the properties of the $C_{ij}$ matrix, $\sigma(r)$ can be easily related to the mean Coulomb-energy density by

$$\langle E_C/V \rangle = \frac{\sigma(0)}{r} + \lambda \sum_{j \neq 0} V \frac{\sigma(r_{ij})}{r_{ij}}.$$  

Eq. (6) indicates that a diverging correlation length at the critical point manifests by a divergent Coulomb-energy density. When $\beta_C \neq 0$ the only solution for the system to avoid such a singularity is to suppress the second-order critical character of the limiting point [12]. In this case, the correlation length keeps a finite value at the limiting temperature and the thermodynamic limit is fulfilled by a constant value of $\langle E_C/V \rangle$. Such a behaviour is tested in Fig. 2 where the same calculation is repeated for different lattice sizes: the average Coulomb energy is seen to increase with the lattice size in the Ising system, while Coulomb-energy fluctuations appear quenched in the frustrated system. It is interesting to note that this argument does not apply in other neutral Coulombic systems [21], where density fluctuations do not necessarily imply charge fluctuations, and can therefore diverge keeping a finite Coulomb energy. For the same to be true in the proto-neutron star, the electron field should be strongly polarized at the limiting temperature, leading to a complete charge screening of the dishomogeneous pasta structures. Due to the high incompressibility of the degenerate electron gas, this is likely to be unphysical [12].

The quenching of criticality can be formally verified in terms of critical exponents. If the asymptotic value of the limiting temperature $T_{\text{lim}} = \lim_{L \to \infty} \bar{T}_{\text{lim}}(L)$ corresponds to a critical point, finite-size scaling insures that $\bar{T}_{\text{lim}}(L)$ should evolve as $\bar{T}_{\text{lim}}(L) - T_{\text{lim}} \propto L^{-1/\nu}$ [22]. Fig. 3 illustrates that, while the scaling is respected with the Ising value of $\nu$ when $\beta_C = 0$, $\nu$ should be infinitely large to describe the frustrated system. Since $\nu$ rules the divergence of the correlation length, $\xi \propto t^{-\nu}$ with $t = T/T_{\text{lim}} - 1$, this is a first indication of a finite correlation length for the charged system. We then test the finite-size scaling theory [22] on the quantity $\chi = \sum_{ij} \sigma_{ij}/T$. This form of $\chi$ represents the susceptibility only for $T \geq \bar{T}_{\text{lim}}(L)$. In this case, it should scale with the critical exponent $\gamma$ as $L^{-\gamma/\nu} \chi = f(L^{1/\nu})$ if

FIG. 2: (Color online) Probability distribution for the two energy components $E_n, E_C$ for the four points indicated in Fig. 3. Contour plots refer to $L = 10$; logarithmic cluster plots refer to $L = 20$. Points (1) and (3) belong to the coexistence region and manifest bimodal patterns. Both point (2) and (4) are very close to the limiting temperature but the critical scaling effects exhibited at point (2) are absent at point (4).
the limiting point represented a critical point; the function $f(L^{-1/\nu t})$ should be constant when $\xi \sim L$ and $f(L^{-1/\nu t}) \propto (L^{1/\nu})^{-\gamma}$ when $\xi \ll L$. When $T < \tilde{T}_{\text{lim}}(L)$, $\chi$ contains also jumps between the low-density, $\langle n \rangle_G$, and the high-density, $\langle n \rangle_L$, solutions and should therefore scale with the critical exponent $\beta$ defined from the scaling of the order parameter $\langle n \rangle_L - \langle n \rangle_G \propto \epsilon$ as $\chi \propto L^{D \nu_\epsilon \beta}$. By introducing the hyperscaling relation $D = (\gamma + 2\beta)/\nu$, all scaling laws condense in the form

$$L^{-\gamma/\nu} \propto \begin{cases} \text{constant} & \text{as } \xi \sim L \\ (L^{1/\nu})^{-\gamma} & \text{as } \xi \ll L, \ T \geq \tilde{T}_{\text{lim}}(L) \\ (L^{1/\nu})^{\gamma \beta} & \text{as } \xi \ll L, \ T < \tilde{T}_{\text{lim}}(L) \end{cases} (7)$$

Fig. 3C illustrates the perfect consistency of the $\beta_C = 0$ system with Ising critical exponents. Conversely, for the charged system, no combination of $\beta$, $\gamma$, and $\nu$ can be found to let all calculated points collapse on the same law. In particular, for $\gamma/\nu = 0$ and $\nu \rightarrow \infty$, only the points for $T \gg \tilde{T}_{\text{lim}}(L)$ collapse on one line, while those for $T \ll \tilde{T}_{\text{lim}}(L)$ disperse as shown in Fig. 3B. This demonstrates that the effect of the Coulomb field is not a simple increase of the $\nu$ exponent, but a complete quenching of criticality for the frustrated system. The loss of critical behaviour has been already observed in Ising models for the Ising frustrated ferromagnet, eq. (2), where the coexistence region was seen to end at a first-order point [3].

Our conclusion is twofold. First, we observed that, in presence of a uniform electron background, the Coulomb field originating from charge-density fluctuations increases the limiting temperature for phase coexistence, at variance with the strong decrease obtained in the absence of electrons or in mean-field calculations [19, 20]. Therefore, the mixed-phase phenomenology may be relevant for the proto-neutron-star structure up to slightly above the critical temperature of normal nuclear matter ($T_c \approx 15$ MeV for symmetric matter), in a wider temperature-range than usually expected [2]. Second, the Coulomb field suppresses the critical character of the limiting temperature. For this reason we expect warm stellar matter to show small opacity to neutrino scattering in agreement with the findings of ref. [23].
