Local Administration of Insulin-like Growth Factor I into Silicon Rubber Chamber Improves Peripheral Nerve Repair in Rats

Abstract

Introduction: Organ reinnervation and functional recovery following peripheral nerve injury still remains a major challenge and return of functional recovery to the preinjured level rarely occurs. The aim was to evaluate the effect of locally administered insulin-like growth factor (IGF I) on nerve regeneration.

Methods: Eighty male white Wistar rats were divided into four groups (n = 20), randomly: In transected group (TC), left sciatic nerve was transected and stumps were fixed in the adjacent muscle. In treatment group defect was bridged using a silicone conduit (SIL/IGF) and filled with 10 µL IGF I (100 ng/kg). In silicone graft group (SIL), the graft was filled with phosphate-buffered saline alone. In sham-operated group (SHAM), sciatic nerve was exposed and manipulated. Each group was subdivided into three subgroups of five animals each and studied 4, 8 and 12 weeks after surgery.

Results: Behavioral testing, sciatic nerve functional study, gastrocnemius muscle mass and morphometric indices confirmed faster recovery of regenerated axons in SIL/IGF than in SIL group (p < 0.05). In immunohistochemistry, location of reactions to S-100 in SIL/IGF was clearly more positive than that in SIL group.

Conclusion: When loaded in a silicone graft, IGF I accelerated and improved functional recovery and morphometric indices of sciatic nerve. Thus, dose–response studies should be conducted for IGF I to determine the combination of the graft and the compound that achieve maximal efficacy in nerve transection models.

It has been reported that using silicone tubes in bridging of nerve defects could be promising because it is inert and does not induce extensive scarring or degeneration after implantation [6]. The advantages like no donor morbidity, availability, affordability and no foreign reactions make silicone rubber chamber an attractive alternative compared to other standard grafts [7]. It has been demonstrated that silicone rubber tubes are well tolerated in humans even after 3 years of implantation [8]. Silicone chambers are used as standard experimental model to study the nerve regeneration process [9].

Neurotrophic factors are a family of growth factors that support and influence the growth and regenerative capacity of neurons. These substances are produced by tissues during development and direct the formation of the brain and spinal cord and their connections to target organs such as muscle [10-12]. In adults IGF-I immunoreactivity is detectable in the ventral horn, sympathetic and dorsal root ganglia in the adult rat, and axons and Schwann cells of the sciatic nerve [13,14]. During development, both motor and sensory neurons also respond to IGF-I and -II with increased neurite outgrowth [14,15-18]. Schwann cell is an essential cellular component of peripheral nerve and a source of IGF after nerve injury. IGFs are also important factors in Schwann cell biology. IGF-I is a potent mitogen for Schwann cells in culture [19-21]. IGF-I promotes not only the expression of...
myelin proteins such as Protein zero but also segmental myelination of dorsal root ganglia axons in culture, including the formation of nodes of Ranvier [22]. Promising results regarding beneficial effect of IGF I on peripheral nerve regeneration is not supported by functional tests, to the best knowledge of the authors, which play a crucial role in assessment of functional nerve recovery.

Aimed to study local effects of IGF I on peripheral nerve regeneration, the present study was designed to determine if local IGF could in fact reduce dysfunction after nerve injury in the rat sciatic nerve transection model. Assessment of the nerve regeneration was based on behavioral, functional, histomorphometric and immunohistochemical (Schwann cell detection by S-100 expression) criteria 4, 8 and 12 weeks after surgery.

**Materials and Methods**

**Study design and animals**

Eighty male Wistar rats weighing approximately 300g were divided into four experimental groups (n = 15), randomly: sham-operation group as normal control (SHAM), transected control (TC), silicone conduit (SIL) and IGF treated group (SIL/IGF). Each group was further subdivided into three subgroups of five animals each and surveyed 4, 8 and 12 weeks after surgery. Two weeks before and during the experiments, the animals were housed in individual plastic cages with an ambient temperature of (23±3) °C, stable air humidity and a natural day/night cycle. The rats had free access to standard rodent laboratory food and tap water. All measurements were made by two blinded observers unaware of the analyzed groups.

**Surgical procedure**

Animals were anesthetized by intraperitoneal administration of ketamine-xylazine (ketamine 5%, 90mg/kg and xylazine 2%, 5mg/kg). The procedure was carried out based on the guidelines of the Ethics Committee of the International Association for the Study of Pain [23]. The University Research Council approved all experiments.

Following surgical preparation in the sham-operation group, the left sciatic nerve was exposed through a gluteal muscle incision and after careful homeostasis the muscle was sutured with resorbable 4/0 sutures, and the skin with 3/0 nylon. In TC group, the left sciatic nerve was transected proximal to the tibio-peroneal bifurcation where a 7mm segment was excised, leaving a 10mm gap due to retraction of nerve ends. Proximal and distal stumps were fixed in the adjacent muscle with 10/0 nylon epineurial suture. No graft was interposed between the stumps. In control group (SIL), the left sciatic nerve was exposed the same way, transected proximal to the tibio-peroneal bifurcation where a 7mm segment was excised, leaving a gap about 10 mm due to retraction of the nerve ends. The proximal and distal stumps were each inserted 2 mm into the conduit and two 10/0 nylon sutures were placed at each end of the cuff to fix the tube in place and leave a 10-mm gap between the stumps. The silicone tube was filled with 10 μL phosphate buffered solution. Sterile Vaseline was used to seal the ends of the tubes to avoid leakage. In IGF treated group (SIL/IGF) the silicone graft was filled with 10 μL IGF I (100ng/kg). All surgical procedures were carried out by the same surgeon, using a sterile microsurgical technique. After surgery had carried out animals were housed in groups of five per cage under the same conditions mentioned above. The animals were anesthetized and euthanized with transcardiac perfusion of a fixative containing 2% paraformaldehyde and 1%glutaraldehyde buffer (pH 7.4) 4, 8 and 12 weeks after surgery.

**Behavioral Testing**

Functional recovery of the nerve was assessed using the Basso, Beattie, and Bresnahan (BBB) locomotor rating scale for rat hind limb motor function [24]. Although BBB is widely used to assess functional recovery in spinal cord injured animals, however, it has been demonstrated that it could be most useful in assessment of never repair processes in peripheral nerve injuries [1]. Scores of 0 and 21 were given when there were no spontaneous movement and normal movement, respectively. A score of 14 shows full weight support and complete limbs coordination. BBB recordings were performed by a trained observer who was blinded to the experimental design. The testing was performed in a serene environment. The animals were observed and assessed within a course of a 4-minute exposure to an open area of a mental circular enclosure. BBB scores were recorded once before surgery in order to establish a baseline control and again weekly thereafter to assess functional recovery during 12 weeks.

**Functional assessment of reinnervation**

**Sciatic functional index (SFI):** Walking track analysis was performed 4, 8 and 12 weeks after surgery based on the method of others [16]. The lengths of the third toe to its heel (PL), the first to the fifth toe (TS), and the second toe to the fourth toe (IT) were measured on the experimental side (E) and the contralateral normal side (N) in each rat. The sciatic function index (SFI) of each animal was calculated by the following formula:

\[
SFI = -38.3 \times (\text{EPL/NPL}) + 109.5 \times (\text{ETS/NTS}) + 13.3 \times (\text{EIT-NIT})/\text{NIT} - 8.8
\]

In general, SFI oscillates around 0 for normal nerve function, whereas around -100 SFI represents total dysfunction. SFI was assessed in the NC group and the normal level was considered as 0. SFI was a negative value and a higher SFI meant the better function of the sciatic nerve.

**Static sciatic index (SSI):** SSI is a time-saving digitized static footprint analysis described by others [25]. A good correlation between the traditional SFI and the newly developed static sciatic index (SSI) and static toe spread factor (TSF), respectively, has been reported by others [25]. The SSI is a time-saving and easy technique for accurate functional assessment of peripheral nerve regeneration in rats and is calculated using the static factors, not considering the print length factor (PL), according to the equation:

\[
SSI = [(108.44 \times \text{TSF}) + (31.85 \times \text{ITSF})] - 5.49
\]

Where:

\[
\text{TSF} = (\text{ETS-NTS})/\text{NTS}
\]

\[
\text{ITSF} = (\text{EIT-NIT})/\text{NIT}
\]

Like SFI, an index score of 0 was considered normal and an index of −100 indicated total impairment. When no footprints were measurable, the index score of −100 was given.
Muscle mass

Recovery assessment was also indexed using the weight ratio of the gastrocnemius muscles 12 weeks after surgery. Immediately after sacrificing of animals, gastrocnemius muscles were dissected and harvested carefully from intact and injured sides and weighed while still wet, using an electronic balance.

Histological preparation and morphometric studies

Nerve mid-substance in SIL group, nerve mid-substance in IGF I treated group, midpoint of normal sciatic nerve (Sham) and regenerated mid substance of TC group were harvested and fixed with glutaraldehyde 2.5%. They were post fixed in OsO4 (2%, 2 h), dehydrated through an ethanol series and embedded in Epon. The nerves were cut in 5 μm in the middle, stained with toluidine blue and examined under light microscopy. Morphometric analysis was carried out using an image analyzing software (Image-Pro Express, version 6.0.0.319, Media Cybernetics, Silver Springs, MD, USA). Equal opportunity, systematic random sampling and two-dimensional dissector rules were followed in order to cope with sampling-related, fiber-location-related and fiber-size related biases [26].

Immunohistochemical analysis

In this study, anti-S-100 (1:200, DAKO, USA) was used as marker for myelin sheath. Specimens were post fixed with 4% paraformaldehyde for 2h and embedded in paraffin. Prior to immunohistochemistry nerve sections were dewaxed and rehydrated in PBS (pH 7.4). Then the nerve sections were incubated with 0.6% hydrogen peroxide for 30 minutes. To block non-specific immunoreactions the sections were incubated with normal swine serum (1:50, DAKO, USA). Sections were then incubated in S-100 protein antibody solution for 1h at room temperature. They were washed three times with PBS and incubated in biotynilated anti-mouse rabbit IgG solution for 1h. Horseradish peroxidase-labelled secondary antibody was applied for 1 h. After that all sections were incubated with 3,3’- diaminobenzidine tetrahydrochloride chromogene substrate solution (DAB, DAKO, USA) for 10 min. The results of immunohistochemistry were examined under a light microscope.

Statistical Analysis

The results were expressed as means ± SD. Statistical analyses were performed using PASW 18.0 (SPSS Inc., Chicago, IL, USA). Model assumptions were evaluated by examining the residual plot. Results were analyzed using a factorial ANOVA with two between-subjects factors. Bonferroni test for pairwise comparisons was used to examine the effect of time and treatments. The differences were set at P<0.05.

Results

Behavioral Testing

BBB recovery: In order to assess hind limb recovery the open field locomotor was used. Figure 1 shows BBB scores compared to the baseline. All experimental groups, except for Sham, showed the greatest degree of functional deficit one week after surgery. The IGF I treated group showed significant improvement in locomotion of the operated limb compared to the SIL group during the study period (P<0.05).

Recovery of sciatic nerve function

SFI outcome: Figure 2 shows sciatic function index (SFI) values in all four experimental groups. Prior to surgery, SFI values in all groups were near zero. After the nerve transaction, the mean SFI decreased to -100 due to the complete loss of sciatic nerve function in all animals. At the end of the study period, animals of IGF I group achieved a mean value for SFI of -45.8 ± -2.36 where as in group SIL a mean value of -63.3 ± -3.14 was found. The statistical analyses revealed that the recovery of nerve function was significantly (P < 0.05) different between SIL/IGF and SIL groups and application of the IGF I in silicone conduit significantly accelerated functional recovery in the course of time.

SSI outcome: Changes in SSI were similar to those observed in SFI, indicating significant deficit following the sciatic nerve transaction (Figure 3). Changes in SSI were significant at weeks 4, 8 and 12 of recovery (P < 0.05). The contrasts indicate SSI values in group SIL/IGF at week 12 to differ significantly from those obtained from SIL, a trend also noticed for SFI (P < 0.05).

Muscle mass measurement

The mean ratios of gastrocnemius muscle weight were measured at the end of the study period. There was a statistically significant difference between the muscle weight ratios of the SIL/IGF and SIL groups (P < 0.05). The results showed that in the IGF I treated group, the muscle weight ratio was larger than in the SIL group, and weight loss in the gastrocnemius muscle was ameliorated by IGF I local administration (Figure 4).

Histological and Morphotropic findings

The IGF I treated group presented significantly greater nerve fiber, axon diameter, and myelin sheath thickness during study period, compared to SIL animals (P < 0.05). Sham-operation group presented significantly greater nerve fiber and axon diameter, and myelin sheath thickness compared to SIL/IGF and SIL groups animals (Figures 5-8). In case of myelin thickness there was no significant difference between SIL/IGF and SIL groups, morphometrically (P>0.05).
nerve during the study period. Left gastrocnemius muscle weight was significantly greater in the SIL/IGF group than in the SIL group, indicating indirect evidence of successful end organ reinnervation in the IGF I treated animals. At week 12 quantitative morphometrical indices of regenerated nerve fibers showed significant differences between the SIL and SIL/IGF groups, indicating a beneficial effect of local application of IGF I on the nerve regeneration.

Although both morphological and functional data have been used to assess neural regeneration after induced crush injuries, the correlation between these two types of assessment is usually poor [27-29]. Classical and newly developed methods of assessing nerve recovery, including histomorphometry, retrograde transport of horseradish peroxidase and retrograde fluorescent labeling [29] do not necessarily predict the reestablishment of motor and sensory functions [28,30-32]. Although such techniques are useful

**Discussion**

The results of the present study showed that application of IGF I in a silicone graft resulted in faster functional recovery of the sciatic nerve during the study period. Left gastrocnemius muscle weight was significantly greater in the SIL/IGF group than in the SIL group, indicating indirect evidence of successful end organ reinnervation in the IGF I treated animals. At week 12 quantitative morphometrical indices of regenerated nerve fibers showed significant differences between the SIL and SIL/IGF groups, indicating a beneficial effect of local application of IGF I on the nerve regeneration.

Although both morphological and functional data have been used to assess neural regeneration after induced crush injuries, the correlation between these two types of assessment is usually poor [27-29]. Classical and newly developed methods of assessing nerve recovery, including histomorphometry, retrograde transport of horseradish peroxidase and retrograde fluorescent labeling [29] do not necessarily predict the reestablishment of motor and sensory functions [28,30-32]. Although such techniques are useful
A wide variety of materials have been used to produce nerve guides, including non-biodegradable and biodegradable materials. Because of its inert and elastic properties, the silicon tube was one of the first and most frequently used to bridge the transected nerves [33].

The accumulation of IGF-I after peripheral nerve damage could be the result of disrupted axonal transport or a local therapeutic response. The relevance of post injury up-regulation of IGF has been addressed in multiple studies. Others in an experimental study without being supported by functional tests concluded that local infusion of IGF-I at appropriate concentration promotes regeneration of a peripheral nerve [34]. Kanje et al. [35] reported that IGF-I significantly increased axonal regeneration by 49% in a rat sciatic nerve crush/ transection model. This effect was unique to IGF-I because nerve growth factor treatment had no effect. The in vivo mechanisms of IGF action are assumed to be similar to those activated in primary neuronal cultures. Studies applying pathway-specific inhibitors are not available, however, antibodies to IGF-I but not nerve growth factor or insulin have completely blocked the ability of IGF-I to promote axonal regrowth [35,36]. Further work by others has examined the effects of a preconditioning transection that was performed before nerve crush [37]. Under these conditions, regeneration was more robust than crush alone. This augmented regeneration was blocked by inhibitors of protein or RNA synthesis or retrograde axonal transport [37]. Perfusion of IGF-I is able to overcome the effects of cycloheximide (protein synthesis inhibitor), indicating that locally produced IGF-I is retrogradely transported to the cell body in which it exerts its positive effects [37].

in studying the nerve regeneration process, they generally fail in assessing functional recovery [28]. Therefore, research on peripheral nerve injury needs to combine both functional and morphological assessment. Castaneda et al. [32] suggested that arrival of sprouts from the proximal stump at the distal nerve stump does not necessarily imply recovery of nerve function. Information taken from BBB scale may be invaluable in evaluation of peripheral nerve process. Results of the present study showed that the IGF treated animals had been improved in locomotion of the operated limb compared to the SIL group during the study period. Walking track analysis has frequently been used to reliably determine functional recovery following nerve repair in rat models [16,30].

Figure 6: The graph shows the quantitative results of mean diameter of nerves fibers. The mean diameter of nerve fibers in SHAM group was nearly 12.4 ± 0.14 (mean ± SE). Both groups of SIL and SIL/IGF showed the lower mean diameter of nerve fibers than the sham-operated group even at the end of the study.

Figure 7: The graph shows the quantitative results of mean thickness of myelin sheath. The mean thickness of myelin sheath in SHAM group was nearly 2.5 ± 0.03 (mean ± SE). Both groups of SIL and SIL/IGF showed the lower mean diameter of axons than the sham-operated group even at the end of the study period.

Figure 8: Immunohistochemical analysis of the regenerated nerves 16 weeks after surgery from (A) middle cable TC, (B) SIL, (C) SIL/IGF and (D) SHAM. There is clearly more positive staining of the myelin sheath-associated protein S-100 (arrows) within the periphery of nerve, indicating well organized structural nerve reconstruction in IGF I treated nerve compared to that of the SIL. Scale bar: 10μm.
Even though our preliminary study shows the neuroprotective action of local IGF I in peripheral nerve injuries, determining the molecular mechanisms leading to the neuroprotective action remains to be investigated. We have not given the histological and molecular evidence for neuroprotective action of IGF I. This may be considered as a limitation to our study. Therefore, the authors stress that the aim of the current investigation was to evaluate a single local dose and clinical treatment potential of IGF I on nerve regeneration including functional assessments of the nerve repair, a case not considered in previous studies. The results of the present study indicated that a single Local administration of IGF I at the site of transected nerve could be of benefit after artery graft tubulization. Detailed mechanism of neuroprotective action remains to be investigated.

Conclusion

The present study demonstrated that a single local application of IGF I could accelerated functional recovery after transection of sciatic nerve. Thus, dose–response studies should be conducted for IGF I to determine the combination of the graft and the compound that achieve maximal efficacy in nerve transection models.
