Sciatric neuropathy and rhabdomyolysis after carbon monoxide intoxication

A case report

Hyeok Dong Lee, MD, Sung Young Lee, MD, Young-Shin Cho, MD, Seung Hoon Han, MD, PhD, Si-Bog Park, MD, PhD, Kyu Hoon Lee, MD, PhD

Abstract

Rationale: Peripheral neuropathy is a rare complication of carbon monoxide intoxication. Peripheral neuropathy following carbon monoxide intoxication is known to completely recover within a few months.

Patient concerns: A 40-year-old man complained of motor weakness and hypoesthesia of the right lower extremity with swelling of his right thigh after carbon monoxide intoxication resulting from a suicide attempt.

Diagnoses: Following nerve conduction and electromyographic studies, the patient was diagnosed with sciatric neuropathy with severe axonopathy. Clinical and laboratory findings led to a diagnosis of rhabdomyolysis.

Interventions: The patient was treated conservatively for rhabdomyolysis and underwent comprehensive rehabilitation for sciatric neuropathy during hospitalization.

Outcomes: After discharge, he underwent serial follow-up tests with nerve conduction and electromyographic studies, which showed prolonged persistence of sciatric neuropathy; however, he showed significant improvement at his 26-month post-discharge follow-up.

Lesson: Patients presenting with peripheral neuropathy secondary to carbon monoxide intoxication may show variable recovery periods; however, a favorable prognosis can be expected regardless of the concomitant occurrence of rhabdomyolysis and/or compartment syndrome.

Abbreviations: AFO = ankle-foot orthoses, CMAP = compound muscle action potential, EMG = electromyography, MMT = manual muscle testing, MRI = magnetic resonance imaging, NCS = nerve conduction study.

Keywords: carbon monoxide intoxication, electromyography, rhabdomyolysis, sciatric neuropathy

1. Introduction

Carbon monoxide intoxication had been reported in Korea until the 1980s when briquettes were widely used for heating and cooking purposes; however, the replacement of briquettes with oil and gas as fuel has led to a decline in the occurrence of carbon monoxide intoxication. Recently, charcoal-burning suicide rates have reduced due to the replacement of briquettes with oil and gas; however, the replacement of briquettes with oil and gas as fuel has led to a decline in the occurrence of carbon monoxide intoxication. Recently, charcoal-burning suicide rates have reduced due to the replacement of briquettes with oil and gas. Nevertheless, the rate of peripheral neuropathy to be 0.84% in 2360 patients diagnosed with carbon monoxide intoxication, and previous studies have reported the prevalence rate of peripheral neuropathy to be 0.84% in 2360 patients diagnosed with carbon monoxide intoxication. Peripheral neuropathy caused by carbon monoxide intoxication is known to show complete recovery within a few months. Furthermore, to our knowledge, no report has described a case of peripheral neuropathy secondary to carbon monoxide intoxication, wherein the patient has not recovered within a year. We describe the case of a patient diagnosed with sciatric neuropathy after carbon monoxide intoxication secondary to a charcoal-burning suicide attempt, who showed significant recovery at his 26-month post-discharge follow-up examination.

2. Case presentation

A 40-year-old man presented to the emergency department from another hospital with a swelling of his right thigh after a charcoal-burning suicide attempt in his car. He had been rescued after having remained in the car for 4 hours and received hyperbaric oxygen therapy at the previous hospital. When he arrived at the emergency department, physical examination revealed motor weakness and hypoesthesia of his right lower extremity and anesthesia of his right foot. Manual muscle testing (MMT) showed the following strengths of his individual muscle group: hip flexors, and extensors and knee flexors, grade 2; knee...
extensors, grade 3; ankle dorsi-flexors and great toe dorsi-flexors, grade 1; and ankle plantar-flexors, grade 0. The circumference of his right thigh was 63 cm, which was 14 cm larger than that of the left thigh (Fig. 1). Second-degree burns were observed on his right thigh, upper arm, and scalp. Laboratory investigations showed elevated serum levels of creatine phosphokinase (79,800 U/L), lactate dehydrogenase (1949 U/L), aspartate aminotransferase (1132 U/L), alanine aminotransferase (353 U/L), blood urea nitrogen (41.6), creatinine (2.83 mg/dL), white blood cells (12,400 cells/mm³), C-reactive protein (11.17 mg/dL), and myoglobin (>4000 ng/mL). Magnetic resonance imaging (MRI) showed swelling and diffusely increased signal intensity in the muscles of the right thigh, and also the gluteal muscles with a signal abnormality was observed in the right sciatic nerve (Fig. 2). Additionally, fluid-attenuated inversion recovery-MRI of the brain showed bilateral hyperintensities in the globus pallidus and cerebellum.

Rhabdomyolysis was treated with adequate hydration and urinary alkalization using sodium bicarbonate. Nerve conduction study (NCS) and electromyography (EMG) were performed 3 weeks after admission. The right-sided sural sensory nerve action potential and the peroneal and tibial compound muscle action potential (CMAP) were unobtainable after performing the NCS. Additionally, the right-sided tibial F-wave response and the H-reflex could not be obtained. Abnormal spontaneous activity was observed in the right medial gastrocnemius, peroneus longus, anterior tibialis, and biceps femoris. On the basis of these results, he was diagnosed with sciatic neuropathy with severe axonopathy. He was discharged after receiving comprehensive rehabilitation for 3 weeks. At the time of discharge, his hip flexor and extensor strength had improved to grade 3 (based on MMT), and he was able to walk with a cane wearing ankle-foot orthoses (AFO). The circumference of his right thigh was nearly the same as that of his left thigh and measured 51 cm. However, there was no improvement in the strength of his ankle dorsi-flexors and plantar-flexors, and also his great toe dorsi-flexors. After discharge, he did home exercise without physical therapy session. Although he underwent follow-up NCS and EMG testing 4 times after discharge, MRI was not performed. EMG performed 2 months after discharge showed newly developed abnormal spontaneous activity in his gastrocnemius muscle. EMG performed 10 months after discharge showed no difference except an improved interference pattern, and newly developed polyphasic motor unit action potential patterns were observed in the long and short head of the biceps femoris muscle. MMT showed an improvement in the strength of the right knee flexors and ankle plantar-flexors to grade 3+ and 2, respectively; however, weakness of his ankle dorsi-flexors and great toe dorsi-flexors persisted. At 21 months after discharge, the strength of right ankle dorsi-flexors was improved to grade 2+ on MMT. Moreover, NCS now showed a small amplitude of the right peroneal CMAP recorded over the tibialis anterior, in contrast to previous testing that had not shown any response in the right peroneal CMAP. The amplitudes recorded were 0.8 and 0.5 mA, respectively, after stimulation at the fibular head and the popliteal fossa. MMT performed 26 months after discharge showed that the strength of his right-sided dorsiflexors had significantly improved to grade 4. The amplitudes of peroneal CMAP recorded over the tibialis anterior were 2.3 mA at both the sites that were stimulated. Table 1 and Table 2 show the summary of the results of NCS and EMG test mentioned above. Notably, the patient was now able to walk independently without using an AFO, and we could conclude that his sciatic neuropathy was in the process of recovery. Considering that the results of NCS and EMG test appear after clinical improvement, it is expected that further examination will show better results.

Written informed consent was obtained for publication of this case report from the patient. The Ethics Approval/Institutional
Review Board (IRB) is not needed because this is not a case of new intervention is performed.

3. Discussion

The pathomechanisms causing peripheral neuropathy secondary to carbon monoxide intoxication are as follows: toxicity of carbon monoxide itself, nerve compression, ischemia related to hypoxia, and petechial hemorrhages.[2,4] Choi[5] suggested that peripheral neuropathy is usually associated with local swelling secondary to muscle necrosis, which is an important factor contributing to the development of peripheral neuropathy after carbon monoxide intoxication. Rahmani et al[6] reported bilateral brachial plexus injury after carbon monoxide intoxication after failed use of a water heater. They attributed the bilateral plexopathy to a combination of ischemic and toxic factors. In our patient, the onset of sciatic neuropathy could be attributed to the

Figure 2. Magnetic resonance imaging (MRI) of the right thigh shows a diffusely increased signal intensity of the muscles of the right thigh and gluteal muscles, with abnormal signal changes in the right sciatic nerve.

BF-L = biceps femoris long head, BF-S = biceps femoris short head, DI = decreased interference patterns, F = fibrillation potential, GCM = medial gastrocnemius, LA = large amplitude, LD = large duration, N/C = not checkable due to low volitional activity, Nml = normal, P = positive sharp wave, PL = peroneus longus, Poly = polyphasic motor unit action potential, RR = reduced recruitment, Rt = right, TA = tibialis anterior.
toxicity of carbon monoxide itself in that carbon monoxide-induced hypoxia may have led to nerve damage. Additionally, direct nerve hypoxia and ischemic damage to the nerve owing to decreased blood flow could have contributed to the development of sciatic compression and ischemic damage to the nerve. However, it is difficult to attribute the pathomechanism to only 1 of the aforementioned hypotheses, and a multifactorial theory appears more plausible.

Carbon monoxide intoxication is an important cause of rhabdomyolysis and compartment syndrome.[7–9] Acute renal failure may occur as a result of rhabdomyolysis caused by carbon monoxide intoxication.[10,11] Ojike et al.[12] have reported a case of sciatic neuropathy related to acute compartment syndrome after carbon monoxide intoxication in which the patient underwent a fasciotomy. Physical examination performed on this patient a year after admission showed good recovery of the strength of knee extensors from grade 2 to grade 4. Choi[2] reported 20 cases of patients with peripheral neuropathy after carbon monoxide intoxication. Despite the occurrence of local swelling in 10 of these 20 patients and the occurrence of delayed neurological sequelae in 3 of 20 patients, complete recovery was achieved within 3 to 6 months in all patients. The patient reported by Rahmani et al.,[6] who had been diagnosed with bilateral brachial plexus injury after carbon monoxide intoxication, was observed to recover without any sequelae within 4 months. Choi and Lim[13] reported a patient with peripheral neuropathy involving the bilateral lower extremities after carbon monoxide intoxication who did not develop local swelling. Weakness of bilateral knee and ankle extensors and flexors showed recovery within 5 months. Kuo et al.[14] reported on a patient with bilateral femoral neuropathy concomitant with rhabdomyolysis after carbon monoxide intoxication. MMT performed in this patient showed recovery of the strength of knee extensors from grade 2 to grade 4.

In our patient, the sequelae associated with peripheral neuropathy showed prolonged persistence after discharge; however, significant improvement was observed at the 26-month postdischarge follow-up. This finding differs from that of previous reports that describe carbon monoxide intoxication-induced peripheral neuropathy that recovered within a few months. To date, recovery of peripheral neuropathy after a period of prolonged persistence has never been reported. Local swelling is an important factor contributing to the development of peripheral neuropathy after carbon monoxide intoxication. Thus, it can be deduced that peripheral neuropathy concomitant with rhabdomyolysis and compartment syndrome is likely to have a more serious presentation. However, it is difficult to predicate the factor that determine whether peripheral neuropathy is accompanied or not in carbon monoxide intoxication just based on this assumption. Moreover, in the aforementioned patients, peripheral neuropathy showed complete recovery within a few months, regardless of the concomitant presence of rhabdomyolysis and compartment syndrome. As we followed up for a long time, we observed that the sequelae of peripheral neuropathy that occurred after carbon monoxide intoxication, accompanied by severe unilateral compartment syndrome and rhabdomyolysis, persisted for a long period of time, but recovered eventually. In patients presenting with peripheral neuropathy after carbon monoxide intoxication, although the recovery period might differ between cases, the prognosis remains favorable regardless of the concomitant occurrence of rhabdomyolysis and/or compartment syndrome.
