ABSTRACT: We update the study of the production of direct $J/\psi$ in association with a $Z$ boson at the Next-to-Leading Order (NLO) in $\alpha_s$ by evaluating both the yield differential in $P_T$ and the $J/\psi$ polarisation in the QCD-based Colour-Singlet Model (CSM). Contrary to an earlier claim, QCD corrections at small and mid $P_T$ are small if one assumes that the factorisation and the renormalisation scales are commensurate with the $Z$ boson mass. As it can be anticipated, the $t$-channel gluon-exchange ($t$-CGE) topologies start to be dominant only for $P_T \gtrsim m_Z/2$. The polarisation pattern is not altered by the QCD corrections. This is thus far the first quarkonium-production process where this is observed in the CSM. Along the same lines, our predictions for direct $\Upsilon + Z$ are also given.

1 Introduction

A few years ago, non-perturbative effects associated with colour-octet (CO) channels [1–3] were considered to be the only plausible explanation for the numerous puzzles in the predictions of quarkonium-production rates at hadron colliders. The situation has slightly changed since then, with the first evaluations of the QCD corrections [4–8] to the yields of $J/\psi$ and $\Upsilon$ (commonly denoted $Q$ hereafter) produced in high-energy hadron collisions via Colour-Singlet (CS) transitions [9–11]. It is now indeed widely accepted [12–14] that $\alpha_s^4$ and $\alpha_s^5$ corrections to the CSM are significantly larger than $\alpha_s^3$ contributions at mid and large $P_T$ and that they should be taken into account in any analysis of their $P_T$ spectrum. Nowadays, it is not clear anymore that CO channels dominate and they are the only source of quarkonia. As a result, there is no consensus on which mechanisms are effectively at work in quarkonium hadroproduction at high energies, that is at RHIC, at the Tevatron and, recently, at the LHC.

Polarisation predictions for the CS channel are also strongly affected by QCD corrections as demonstrated in [6, 8, 15, 16]. At NLO, $Q$ produced inclusively or in association with a photon are expected to be longitudinally polarised when $P_T$ gets larger, whereas
they were thought to be transversely polarised as predicted at LO in the CSM [17, 18]. Such a drastic change is understood by the dominance of new production topologies. This also explains the significant enhancement in the production rates as observed for increasing $P_T$.

The situation is rather different at low $P_T$, where the CS predictions for $Q$ at LO [9–11] and NLO [4–6] accuracy are of the same magnitude at RHIC energies; this shows a good convergence of the perturbative series. They are also in agreement [19–21] with the existing data from RHIC [22] energy all the way up to that of the LHC [23–30]. CO channels are most likely not needed to account for low $P_T$ data — and thus for the $P_T$ integrated yields. This is at odds with earlier works, e.g. [31], which wrongly assumed that $\chi_c$ feed-down could be the dominant CSM contribution. This is supported further by the results of recent works [32–35] focusing on production at $e^+e^-$ colliders which have posed stringent constraints on the size of $C = +1$ CO contributions which can be involved in hadroproduction at low $P_T$. Finally, this is reminiscent of the broad fixed-target measurement survey of total cross sections [36] which challenged the universality of the CO MEs.

In this paper, we focus on the production of $J/\psi$ (and $\Upsilon$) in association with a $Z$ boson. Whereas this process may give us complementary information on quarkonium production if it happens to be experimentally accessible at the LHC, it also offers an interesting theoretical playground for the understanding of the QCD corrections in quarkonium-production processes. Our motivation was twofold: first, to see if the polarisation pattern of the $J/\psi$ is altered by the QCD corrections at large $P_T$; second, to see how large the effect of new topologies opening at NLO is, by comparing a full NLO computation to a simplified one — NLO* — with a infrared (IR) cut-off and neglecting loops. Our attention has also been drawn to this process by a previous analysis of the yield at NLO [37] which showed an intriguing result where NLO corrections were large at low $P_T$ and getting smaller at large(r) $P_T$. Such a result could only be explained by a negligible contribution from new kinematically enhanced topologies and a large (positive) contribution from loop corrections at low $P_T$. As we shall demonstrate, the conclusion drawn in [37] are misguided by an unconventional choice of the factorisation and renormalisation scales ($\mu_F$ and $\mu_R$), — way below $m_Z$ — and by a $P_T$ range not large enough — compared to $m_Z$ — to be able to

Figure 1. Representative diagrams contributing to $J/\psi$ and $\Upsilon$ (denoted $Q$) hadroproduction with a $Z$ boson in the CSM by gluon fusion at orders $\alpha s^2$ (a), $\alpha s^3$ (b,c,d) and initiated by a light-quark gluon fusion at order $\alpha s^3$ (e). The quark and anti-quark attached to the ellipsis are taken as on-shell and their relative velocity $v$ is set to zero.
observe the dominance of \( t \)-CGE topologies. As a matter of fact, if one chooses a value for the scales commensurate with \( m_Z \), rather than the transverse mass of the \( J/\psi \) as done in \([37]\), the NLO corrections are found to be small at small \( P_T \). On the other hand, for \( P_T \gtrsim m_Z/2 \), the NLO corrections are enhanced by a kinematical factor \( P_T^2 \).

The paper is organised as follows. In sections 2 and 3, we describe the evaluation of the cross section at LO and NLO accuracy in the CSM. We also explain how the partial NLO* yield is evaluated. In section 4, we present our results which we first compare to those from \([37]\) with the same scale choice, at the same energy and in the same kinematical region. Then, we show our predictions in an extended \( P_T \) range for \( \mu_{F,R} \) commensurate with \( m_Z \) and we discuss the ratio NLO over LO. We also study the sensitivity of our prediction on the aforementioned scales. Afterwards, we compare the NLO* yield with the full NLO and we comment on the dependence on the IR cut-off at large \( P_T \) and on the impact of the \( t \)-CGE topologies. In section 5, we analyse the yield polarisation at LO, NLO and NLO*. In section 6, we give and discuss our predictions for \( \Upsilon \). Section 7 gathers our conclusions.

2 Cross section at LO accuracy

In the CSM \([9–11]\), the matrix element to create a \( ^3S_1 \) quarkonium \( Q \) with a momentum \( P_Q \) and a polarisation \( \lambda \) accompanied by other partons, noted \( j \), and a \( Z \) boson of momentum \( P_Z \) is the product of the amplitude to create the corresponding heavy-quark pair, \( \mathcal{M}(ab \rightarrow Q\bar{Q}) \), a spin projector \( N(\lambda|s_1,s_2) \) and \( R(0) \), the radial wave function at the origin in the configuration space, obtained from the leptonic width, namely

\[
\mathcal{M}(ab \rightarrow Q^\lambda(P_Q) + Z(p_Z) + j) = \sum_{s_1,s_2,i,i'} N(\lambda|s_1,s_2) \delta^{ii'} \frac{R(0)}{\sqrt{m_Q} \sqrt{N_c}} \times \mathcal{M}(ab \rightarrow Q_1^{s_1}\bar{Q}_2^{s_2}(p = 0) + Z(p_Z) + j),
\]

where \( P_Q = p_Q + p_\bar{Q}, p = (p_Q - p_\bar{Q})/2, s_1 \) and \( s_2 \) are the heavy-quark spins, and \( \delta^{ii'}/\sqrt{N_c} \) is the projector onto a CS state. \( N(\lambda|s_1,s_2) \) can be written as \( \frac{\epsilon_\lambda^\mu}{2\sqrt{2m_Q}} \bar{v}_Q(P_Q, s_2)\gamma^\mu u(Q, s_1) \) in the non-relativistic limit with \( \epsilon_\lambda^\mu \) being the polarisation vector of the quarkonium. Summing over the quark spin yields to traces which can be evaluated in a standard way.

At LO, there is only a single partonic process at work, namely \( g g \rightarrow J/\psi Z \) — completely analogous to \( g g \rightarrow J/\psi\gamma \) for \( J/\psi \)-prompt photon associated production — with 4 Feynman graphs to be evaluated. One of them is drawn on figure 1 (a). The differential partonic cross section is readily obtained from the amplitude squared,\(^1\)

\[
\frac{d\hat{\sigma}}{d\hat{t}} = \frac{1}{16\pi s^2} |\mathcal{M}|^2,
\]

from which one obtains the double differential cross section in \( P_T \) (\( P_T \equiv P_{J/\psi,T} \)) and the \( J/\psi \) rapidity, \( y \), for \( pp \rightarrow J/\psi Z \) after convolution with the gluon PDFs and a change of

\(^1\)The momenta of the initial gluons, \( k_{1,2} \), are, as usual in the parton model, related to those of the colliding hadrons \((p_{1,2})\) through \( k_{1,2} = x_{1,2} p_{1,2} \). One then defines the Mandelstam variables for the partonic system: \( \hat{s} = s x_{1,2}, \hat{t} = (k_1 - P_{J/\psi})^2 \) and \( \hat{u} = (k_2 - P_{J/\psi})^2 \).
variable:
\[
\frac{d\sigma}{dydP_T} = \int_{x_1^{\text{min}}}^1 dx_1 \frac{2sP_T g(x_1, \mu_F) g(x_2(x_1), \mu_F)}{\sqrt{s(\sqrt{s}x_1 - m_T e^y)}} \frac{d\hat{\sigma}}{d\hat{t}},
\]
where \(x_1^{\text{min}} = \frac{m_T \sqrt{\sigma_s - m_{J/\psi}^2 + m_Z^2}}{\sqrt{s(\sqrt{s} - m_{J/\psi})}}\), \(m_T = \sqrt{m_{J/\psi}^2 + P_T^2}\).

3 Cross section at NLO accuracy

The NLO contributions can be divided in two sets: one gathers the virtual corrections which arise from loop diagrams, the other gathers the real (emission) corrections where one more particle appears in the final state. In the next sections, we briefly describe how these are computed.

3.1 Virtual corrections

The computation of the virtual corrections involves three types of singularities: the ultraviolet (UV), the infrared (IR) and the Coulomb ones. UV divergences arising from self-energy and triangle diagrams are cancelled after renormalisation. A similar renormalisation scheme as in ref. [39] is used, except for the fact that, in the present study, the bottom quark is also included in the renormalisation of the gluon field. The renormalisation constants \(Z_m, Z_2\) and \(Z_3\) which are associated to the charm quark mass \(m_c\), the charm field \(\psi_c\) and the gluon field \(A_\mu\) are defined in the on-mass-shell (OS) scheme while \(Z_g\), for the QCD gauge coupling constant \(\alpha_s\), is defined in the modified minimal-subtraction (MS) scheme taking the dimension \(d = 4 - 2\epsilon\):

\[
\begin{align*}
\delta Z_{OS}^m &= -3 C_F \frac{\alpha_s}{4\pi} \left[ \frac{1}{\epsilon_{UV}} - \gamma_E + \ln \frac{4\pi \mu^2}{m_c^2} + \frac{4}{3} \right], \\
\delta Z_{OS}^2 &= -C_F \frac{\alpha_s}{4\pi} \left[ \frac{1}{\epsilon_{UV}} + \frac{2}{\epsilon_{IR}} - 3\gamma_E + 3 \ln \frac{4\pi \mu^2}{m_c^2} + 4 \right], \\
\delta Z_{OS}^3 &= \frac{\alpha_s}{4\pi} \left[ \left( \beta'_0 - 2 C_A \right) \left( \frac{1}{\epsilon_{UV}} - \frac{1}{\epsilon_{IR}} \right) - \frac{4}{3} T_F \left( \frac{1}{\epsilon_{UV}} - \gamma_E + \ln \frac{4\pi \mu^2}{m_c^2} \right) - \frac{4}{3} T_F \left( \frac{1}{\epsilon_{UV}} - \gamma_E + \ln \frac{4\pi \mu^2}{m_b^2} \right) \right], \\
\delta Z_{MS}^g &= -\frac{\beta_0}{2} \frac{\alpha_s}{4\pi} \left[ \frac{1}{\epsilon_{UV}} - \gamma_E + \ln \left( \frac{4\pi \mu^2}{\mu_R^2} \right) \right],
\end{align*}
\]

where \(\gamma_E\) is Euler’s constant, \(\beta_0 = \frac{11}{3} C_A - \frac{4}{3} T_F n_f\) is the one-loop coefficient of the QCD beta function and \(n_f\) is the number of active quark flavours. We take the three light quarks \(u, d, s\) as massless and consider the quarks \(c\) and \(b\) as heavy; therefore \(n_f=5\). In SU(3)_c, we have the following colour factor: \(T_F = \frac{1}{2}, C_F = \frac{4}{3}, C_A = 3\). Finally, \(\beta'_0 \equiv \beta_0 + \frac{8}{3} T_F = \frac{11}{3} C_A - \frac{4}{3} T_F n_f\) where \(n_f = n_f - 2 = 3\) is the number of light quark flavours.

After having fixed our renormalisation scheme, there are 111 virtual-correction diagrams, including counter-term diagrams. Diagrams that have a virtual gluon line connecting the charm quark pair forming the \(J/\psi\) lead to Coulomb singularity \(\sim \pi^2/|p|\), which can be isolated and mapped into the \(c\bar{c}\) wave function. As dimensional regularisation is
adopted and $p$ is set to zero before loop integrals, the Coulomb singularity automatically disappears in the calculation of the short-distance coefficient.

The loop integration has been carried out thanks to the newly upgraded Feynman Diagram Calculation (FDC) package [40], with the implementation of the reduction method for loop integrals proposed in ref. [41].

### 3.2 Real corrections

The real corrections arise from three parton-level sub-processes:

\[
g + g \to J/\psi + Z + g, \quad (3.2)
\]

\[
g + q(\bar{q}) \to J/\psi + Z + q(\bar{q}), \quad (3.3)
\]

\[
q + \bar{q} \to J/\psi + Z + g, \quad (3.4)
\]

where $q$ denotes light quarks with different flavours ($u, d, s$). The charm-gluon fusion contribution may be non-negligible in the presence of intrinsic charm. It will be considered in a separate work.

The contribution from the quark-anti-quark fusion (eq. (3.4)) is IR finite and small. The phase-space integration of the other two sub-processes will generate IR singularities, which are either soft or collinear and which can be conveniently isolated by slicing the phase space into different regions. We use the two-cutoff phase-space-slicing method [42], which introduces two small cutoffs to decompose the phase space into three parts. The real cross section can then be written as

\[
\sigma^{\text{Real}} = \sigma^{\text{Soft}} + \sigma^{\text{Hard Collinear}} + \sigma^{\text{Hard Noncollinear}}. \quad (3.5)
\]

The hard noncollinear part $\sigma^{\text{Hard Noncollinear}}$ is IR finite and can be numerically computed using standard Monte-Carlo integration techniques. Only the real sub-process of eq. (3.2) contains soft singularities. Collinear singularities appear in both real sub-processes of eq. (3.2) and eq. (3.3), but only as initial-state collinear singularities. As shown in ref. [42], all these singularities can be factored out analytically in the corresponding regions. When combined with the IR singularities appearing in the virtual corrections (see section 3.1), the soft singularities of the real part cancel. Yet, some collinear singularities remain. These are fully absorbed into the redefinition of the parton distribution function (PDF): this is usually referred to as the mass factorisation [43]. All the singularities are thus eventually analytically cancelled. After the cancellation, the dependence on the scale $\mu$ vanishes, and the dependences on $\mu_R$ and $\mu_F$ survives.

### 3.3 NLO* cross section

In order to evaluate the NLO* contributions, we use the framework described in [44] based on the tree-level matrix-element generator MADONIA\(^2\) slightly tuned to implement an IR cut-off on all light parton-pair invariant mass. The LO cross section has also been checked with MADONIA.

\(^2\)MADONIA can be used online (model “Quarkonium production in SM”) at [45].
The procedure used here to evaluate the leading-$P_T$ NLO contributions is exactly the same as in [8] but for the process $pp \rightarrow J/\psi + Z + \text{jet}$. Namely, the real-emission contributions at $\alpha_3^3$ are evaluated using MADONIA by imposing a lower bound on the invariant mass of any light parton pair ($s_{ij}^{\text{min}}$). The underlying idea in the inclusive case was that for the new channels opening up at NLO which have a leading-$P_T$ behaviour w.r.t. to LO ones (for instance the $t$-CGE), the cut-off dependence should decrease for increasing $P_T$ since no collinear or soft divergences can appear there. For other NLO channels, whose Born contribution is at LO, the cut would produce logarithms of $s_{ij}/s_{ij}^{\text{min}}$, which are not necessarily negligible. Nevertheless, they can be factorised over their corresponding Born contribution, which scales as $P_T^{-8}$, and hence are suppressed by at least two powers of $P_T$ with respect to the leading-$P_T$ contributions ($P_T^{-6}$) at this order. The sensitivity on $s_{ij}^{\text{min}}$ should vanish at large $P_T$. This argument has been checked in the inclusive case for $\Upsilon$ [8] and $\psi$ [12] as well as in association with a photon [16]. Because of the presence of the $Z$ boson mass, it is not a priori obvious that $t$-CGE topologies dominate over the LO ones. It is thus not clear at all how such procedure to evaluate the NLO yield can provide a reliable evaluation of the full NLO of $J/\psi + Z$. In fact, at mid $P_T$, significantly below the $Z$ boson mass, the difference of the $P_T$ dependence of the NLO and LO cross sections is maybe not large enough for the dependence on $s_{ij}^{\text{min}}$ to decrease fast. Having at hand a full NLO computation, we can carry out such a comparison and better investigate the effect of QCD corrections in quarkonium production. This is done after our complete results are presented.

4 Results for $J/\psi + Z$: differential cross section in $P_T$

4.1 Comparison with Mao et al. [37]

In order to compare our results with those of [37], we take $\sqrt{s} = 14$ TeV and $|y_{J/\psi}| < 3.0$. We have set the factorisation and renormalisation scales at the same value, namely $\mu_F = \mu_R = m_{J/\psi} = \sqrt{m_{J/\psi}^2 + P_T^2}$. For the PDF sets, we used CTEQ6l1 for LO evaluations and CTEQ6m for NLO and NLO* evaluations [46]. We also take $\alpha = 1/137$, $|R_{J/\psi}(0)|^2 = 0.91 \text{GeV}^3$, $m_c = 1.5 \text{GeV}$, $m_Z = 91.1876 \text{GeV}$, and $\sin^2(\theta_W) = 0.23116$. Note that the most up-to-date estimate of the wave function at the origin is actually $|R_{J/\psi}(0)|^2 = 0.944 \text{GeV}^3$ as extracted from the leptonic decay widths of $J/\psi$ [38]. Our LO results (also cross-checked with MADONIA) do match with those of [37] (compare both blue curves on figure 2). However, as depicted in figure 2, we are not able to reproduce the NLO results presented in [37]. At low $P_T$, we have found a $K$ factor smaller than one (i.e. the yield at NLO is smaller than at LO) while they obtained a value larger than one.

That being said, a scale close to $m_Z$, rather than the transverse mass of the $J/\psi$ taken in [37], seems more appropriate as done for instance for $Z + b-$jet [47]. This has an important effect on the scale sensitivity, less on the final numbers predicted for the yields, as we shall discuss in the next section.

[^3]: “Inclusive” is used here in opposition to “in association with another detected particle” which is indeed a more exclusive process.

[^4]: See, however, the note added on page 14.
In figure 3, we show the scale sensitivity at low $P_T$ around two different choices of the "default" scale value, $\mu_0$, (a) the transverse mass of the $J/\psi$ and (b) the $Z$ boson mass. We emphasise that we believe the latter choice to be more appropriate owing to the presence of the $Z$ boson in the hard process. One sees that around $m_Z$ (b), the cross section at NLO is more stable, except for a bump at $m_t$ which can be corrected by properly setting the value of $\Lambda$\cite{6} in the running of coupling constant (currently 0.151 MeV with $m_t = 180$ GeV), which matters for $\mu_R > m_t$. The NLO results are clearly unstable at low scales and they may then artificially be enhanced. In the following sections, we investigate further the dependence of the scale sensitivity for different domains of the $J/\psi$ transverse momenta.
4.2 Results for the differential cross section in $P_T$ at $\sqrt{s} = 8$ TeV and 14 TeV

In the following, we show our results for $|y_{J/\psi}| < 2.4$ — the usual $J/\psi$ acceptance for the CMS and ATLAS detectors — at 8 TeV and 14 TeV and for the renormalisation and factorisation scales set at $m_Z$. We have kept the cut $P_{T_{J/\psi}} > 3$ GeV.

The parameters entering the evaluation of the cross section have been taken as follows: $|R_{J/\psi}(0)|^2 = 0.91$ GeV$^2$, $\text{Br}(J/\psi \rightarrow \ell^+\ell^-) = 0.0594$, $m_c = 1.5$ GeV with $m_{J/\psi} = 2m_c$, $m_b = 4.75$ GeV, $\alpha = 1/128$. Our result at $\sqrt{s} = 14$ TeV are depicted on figure 4. The dotted blue line is our LO result and the solid grey line is our prediction at NLO. It is obvious, contrary to what was obtained in \[37\], that the yield at NLO is getting larger than at LO for increasing $P_T$. This is similar to what happens in the inclusive case. This is also indicative that new leading $P_T$ topologies, in particular $t$-CGE, start dominating rather early in $P_T$ despite of the presence of a $Z$ boson in the process. At $P_T = 150$ GeV, the NLO yield is already ten times that of LO.

The dominance of $t$-CGE topologies can be quantified by a comparison with the results from the NLO* evaluation. As aforementioned, because of the $Z$ boson mass, it was not a priori clear that the NLO* evaluation could make any sense here. Indeed, as long as the contribution from the sub-leading $P_T$ topologies are significant, the NLO* would strongly depend on the arbitrary IR cutoff which is used to mimic the effect of the loop contributions which regulate the soft-gluon-emission divergences. We are in a position to

---

$^5$The cross section at 13 TeV is 12 % smaller than at 14 TeV.

$^6$Note that we could have evaluated the cross section for lower $P_T$ where the cross section is well behaved. However, we do not expect — at least in the central region — any experimental measurement to be carried out in this region owing to the momentum cut on the muons because of the strong magnetic fields in the ATLAS and CMS detectors.

$^7$Not to be confused with the cutoff used in the full NLO computation, on which the final results does not depend.
Figure 5. Differential cross section for $J/\psi + Z$ vs. $P_T$ at $\sqrt{s} = 8$ TeV at LO (blue dashed) and NLO (grey solid) with $\mu_F = \mu_R = m_Z$.

check from which $P_T$ the NLO* starts to reproduce the full NLO and becomes to be less sensitive on the IR cut.

The various dotted lines on figure 4 show the NLO* evaluation for different cut-off values. Two observations can be made: 1) they converge to the NLO steadily for increasing $P_T$, 2) for $P_T > m_Z$, the NLO* evaluations are within a factor of 2 compatible with the complete NLO yield. This confirms that loop corrections are sub-leading in $P_T$ and can be safely neglected for $P_T$ larger than all the masses relevant for the process under consideration and that new topologies appearing at NLO, the $t$-CGE ones, dominate at large $P_T$. At low $P_T$, where the NLO and LO yield are similar, the NLO* overestimate the NLO.

As regards the possibility to study such a process at the LHC, the $P_T$ differential cross sections times the branching $\text{Br}(J/\psi \rightarrow \mu^+ \mu^-)$ at the smallest $P_T$ accessible by ATLAS and CMS (3 to 5 GeV depending on the rapidity) is of the order of 1 fb/GeV at 14 TeV (figure 4) and three times less at 8 TeV (figure 5). These do not take into account the branching of the $Z$ in dimuons ($\sim 3\%$). In the most optimistic case, by integrating on the accessible $P_T$ range, by using both muon and electron decay channels for the $J/\psi$, by expecting an indirect cross section of 40 % and by detecting the $Z$ boson with hadronic channels such that it could be detected 40 % of the time, it may be envisioned to detect something like four hundred events at 14 TeV with 100 fb$^{-1}$ of data. At 8 TeV with the 20 fb$^{-1}$ of data expected to be collected in 2012, we expect only about thirty events to be recorded. Clearly, there are more promising processes, such as $J/\psi + \gamma$ [15, 16] or $J/\psi + D$ [19, 48], to learn more on the production mechanisms of the $J/\psi$. Nevertheless, the study of $J/\psi + Z$ may suffer less from trigger limitations and could thus still be at reach at the LHC. In any case, it is an ideal theory playground to analyse the effects of QCD corrections on quarkonium production, which have been the key subject in the recent years in the field.
4.3 Scale sensitivity at different $P_T$

From the observations made above, we expect the real emission contributions at $\alpha_s^3$ to dominate for $P_T \gtrsim m_Z/2$. This should therefore impact on the scale dependence of the yield. At low $P_T$ ($\ll m_Z$), we expect a reduced scale dependence since we really deal with a process at NLO accuracy. At large $P_T$, the leading process is $pp \to J/\psi + Z +$ parton. The loop contributions are not expected to reduce the scale sensitivity since they are small. On the contrary, we expect a larger sensitivity on the renormalisation scale, $\mu_R$, since the leading process shows an additional power of $\alpha_s(\mu_R)$. In practice, we study the scale sensitivity by varying $\mu_F$ and $\mu_R$ together and then $\mu_R$ alone by a factor 2 about the “default” scale $m_Z$ with 3 cuts in $P_T$ — i.e. 3, 50 and 150 GeV.

On figure 6, we do observe, as anticipated for $P_T \gtrsim m_Z$ (red curves), a stronger scale sensitivity of the NLO yield (b) — at $\alpha_s^3$ — than of the LO yields (a) — at $\alpha_s^2$. The NLO curve with $\mu_F$ fixed clearly shows that the sensitivity essentially comes from $\mu_R$. At mid $P_T$ (orange curves), the scale sensitivities are similar at LO and NLO, while at low $P_T$ (black curves), the NLO yield is less scale dependent than the LO — in agreement with the common wisdom regarding the NLO computations. Note also that the 3 LO curves showing the sole dependence on $\mu_R$ are identical since one can factor out a common $\alpha_s^3$ since our choices of $\mu_R$ do not depend on $P_T$.

5 Polarisation: polar anisotropy in the helicity frame

The polar anisotropy of the dilepton decay of the $J/\psi$, $\lambda_\theta$ or $\alpha$, can be evaluated from the polarised hadronic cross sections:

$$\alpha(P_T) = \frac{d\sigma_T}{dP_T} - 2 \frac{d\sigma_L}{dP_T}$$

$$\frac{d\sigma_T}{dP_T} + 2 \frac{d\sigma_L}{dP_T}$$ (5.1)
To evaluate $\alpha(P_T)$, the polarisation of $J/\psi$ must of course be kept throughout the calculation. The partonic differential cross section for a polarised $J/\psi$ is expressed as:

$$d\hat{\sigma}_\lambda = a \epsilon(\lambda) \cdot \epsilon^*(\lambda) + \sum_{i,j=1,2} a_{ij} p_i \cdot \epsilon(\lambda) p_j \cdot \epsilon^*(\lambda),$$  \hspace{2cm} (5.2)$$

where $\lambda = T_1, T_2, L$. $\epsilon(T_1)$, $\epsilon(T_2)$, $\epsilon(L)$ are respectively the two transverse and the longitudinal polarisation vectors of $J/\psi$; the polarisations of all the other particles are summed over. One can find that $a$ and $a_{ij}$ are finite when the virtual and real corrections are properly handled as aforementioned. There is therefore no difference in the partonic differential cross section $d\hat{\sigma}_\lambda/d\hat{t}$ whether the polarisation of $J/\psi$ is summed over in 4 or $n$ dimensions. Thus, we can just treat the polarisation vectors of $J/\psi$ in 4 dimensions. There are usually several different choices of the polarisation frames, as discussed in refs. \cite{49–51}. In our calculation, we have chosen to work in the helicity frame. The polarisation can be obtained in a given frame by taking the corresponding polarisation vectors in eq. (5.2).

Our results at 14 TeV in figure 7 (a) clearly show that the direct-$J/\psi$ yield in association with a $Z$ boson is increasingly longitudinally polarised in the helicity frame for increasing $P_T^{J/\psi}$. The NLO and NLO* results coincide and the latter is nearly insensitive to the IR cutoff. Interestingly, the NLO and the LO results are also very similar. This is the first time that such a robustness of the polarisation against QCD corrections is observed for the colour-singlet channels. For the $J/\psi$ produced inclusively or in association with a photon, the yield at LO and NLO are found to have a completely different polarisation. Our interpretation is that, when a $Z$ boson is emitted by one of the charm quarks forming the $J/\psi$, the latter is longitudinally polarised, irrespective of the off-shellness and of the transverse momentum of the gluons producing the charm-quark pair. This is not so when a photon or a gluon is emitted in the final state. In the present case, we also note that the polarisation at 8 TeV (figure 7 (b)) is nearly exactly the same as at 14 TeV.
6 Results for $\Upsilon + Z$

Along the same lines as for $J/\psi$, we have also evaluated the cross section and the polarisation for direct-$\Upsilon$ production in association with a $Z$ boson. We have set the factorisation and renormalisation scales at the same value, namely $\mu_F = \mu_R = m_Z$, and we used the same PDF sets as for the $J/\psi + Z$ case. We have also taken $\alpha = 1/128$, $|R_{\Upsilon}(0)|^2 = 7.6$ GeV$^3$, $m_b = 4.75$ GeV, $m_Z = 91.1876$ GeV, and $\sin^2(\theta_W) = 0.23116$.

6.1 Tevatron

Experimentally, the CDF Collaboration at Fermilab has set a 95 % C.L. upper value for such a cross section at $\sqrt{s} = 1.8$ TeV \[^{[52]}\], namely

$$\sigma(p\bar{p} \to \Upsilon + Z + X) \times \text{Br}(\Upsilon \to \mu^+\mu^-) < 2.5 \text{ pb.}$$ (6.1)

Further studies with the entire data set recorded by CDF is under process \[^{[53]}\]. At $\sqrt{s} = 1.8$ TeV, a quick evaluation of the total cross section (without $y$ cut, nor $P_T$ cut) gives, for the CSM, a value close to 0.1 fb ($\sim 0.2$ fb by taking into account a similar feed-down fraction ($\sim 50\%$) to that of the inclusive case). A similar evaluation for the CO transitions is highly dependent on the chosen LDME values and on the expected impact of the feed-down. Values span from $\sim 0.06$ fb for the direct yield with CO LDMEs fit \[^{[54]}\] from the early prompt Tevatron data, up to $\sim 3.75$ fb as evaluated in \[^{[55]}\], passing by $\sim 0.4$ fb for the direct yield using CO LDMEs fit from the latest Tevatron results taking into account some NLO QCD corrections \[^{[56]}\]. This is, in any case, significantly below the CDF upper bound obtained with 83 pb$^{-1}$ of data. Given these small theoretical values, we fear that such process cannot be experimentally accessed at the Tevatron, unless contributions from colour-octet transitions, from double-parton interactions or from feed-downs are unexpectedly large.

6.2 LHC

At the LHC at 14 TeV, the expected yield in the CSM for the central rapidity region accessible by CMS and ATLAS is of the order 5 fb (still including the branching of the $\Upsilon$ in muons). The central values for the differential cross sections vs. $P_T$ at LO and NLO are shown in figures 8 (a–c). An enhancement by a factor 2 to 4 can certainly be expected if the feed-downs from excited bottomonium states and the usual theoretical uncertainties are taken into account.

By comparing figures 8 (a–c), one also notices an interesting phenomenon: the NLO and LO yields start to depart from each other at low $P_T$ for increasing $\sqrt{s}$. This can probably be attributed to an increasing — negative — size of the loop corrections in this region at small $x$. This is in fact reminiscent to what has been observed in the inclusive case \[^{[4, 6, 19, 20]}\]. In the latter case, the situation is worse since the NLO cross section can become negative for large $\sqrt{s}$ and small $P_T$.

For the sake of the comparison with the $J/\psi$ case, we have also computed the polarisation at LO and NLO. As it can be seen on figure 9, the yield polarisation at LO and
Figure 8. Differential cross section for direct $\Upsilon + Z$ vs. $P_T$ at LO (blue-dashed) and NLO (grey-solid) with $\mu_F = \mu_R = m_Z$ at 14 TeV (a), 8 TeV (b) and $1.96$ TeV (c).

Figure 9. $P_T$ dependence of the polarisation (or azimuthal anisotropy) in the helicity frame of the direct $\Upsilon$ produced with a $Z$ boson at LO and NLO at $\sqrt{s} = 14$ TeV.

NLO are very alike, though slightly different from for the $J/\psi$ case — most probably due to the change in the quarkonium mass compared to the $Z$ mass.

7 Conclusions

In conclusion, we have studied the effects of the QCD corrections to the production of direct $J/\psi$ and $\Upsilon$ via colour-singlet transitions in association with a $Z$ boson at the LHC. We have found, contrary to an earlier study [37], that the NLO QCD corrections are consistent with the expectations, namely increasing for increasing $P_T$ and small at low $P_T$. We expect that a few hundred $J/\psi + Z$ events could be detected at the LHC at 14 TeV with 100 fb$^{-1}$ of data. At 8 TeV with 20 fb$^{-1}$, there may be just enough events to derive a cross section and not only an upper bound on its value. Interestingly, the CSM yield expected for direct $\Upsilon + Z$ is of the same order of magnitude than that of direct $J/\psi + Z$ at 14 TeV, if not larger.

*We have considered a wider rapidity range than usual for the CDF quarkonium analyses since CMX muons can be used in such a correlation analysis owing to the smaller background compared to inclusive measurements [53].
We have studied the scale sensitivity of the $J/\psi + Z$ cross section at LO and NLO. At low $P_T$, it is smaller when QCD corrections are taken into account. On the contrary, at large $P_T$, i.e. when $P_T \gtrsim m_Z/2$, the dominant contributions are of the kind of $gg \to Q + Z + \text{jet}$. These involve an additional power of $\alpha_s$ and the sensitivity on the renormalisation scale is larger. That being said, the presence of the $Z$ boson mass renders the CSM prediction more precise at low $P_T$ compared to the inclusive case, for which the leading-$P_T$ contributions at NLO dominate at lower $P_T$.

We have also found that the yield polarisation is not altered by the QCD corrections. From this observation, we have concluded that when a $Z$ boson is emitted by one of the heavy quarks forming the quarkonium, both the $J/\psi$ and the $\Upsilon$ are longitudinally polarised at LO and NLO, thus independently of the off-shellness and of the transverse momentum of the gluons producing the heavy-quark pair. This is at odds with the cases of inclusive $Q$ production and $Q + \gamma$ production, and this motivates further theoretical and experimental investigations.

Note added. During the publication process, Mao et al. submitted an erratum where some of their results are corrected [57]. Their NLO results now agree with ours. However, we still disagree with their choice of $\mu_R$ and $\mu_F$.
