THE WEAK LEFSCHETZ PROPERTY FOR MONOMIAL IDEALS OF SMALL TYPE

DAVID COOK II* AND UWE NAGEL

ABSTRACT. In this work a combinatorial approach towards the weak Lefschetz property is developed that relates this property to enumerations of signed perfect matchings as well as to enumerations of signed families of non-intersecting lattice paths in certain triangular regions. This connection is used to study Artinian quotients by monomial ideals of a three-dimensional polynomial ring. Extending a main result in the recent memoir [1], we completely classify the quotients of type two that have the weak Lefschetz property in characteristic zero. We also derive results in positive characteristic for quotients whose type is at most two.

1. Introduction

A standard graded Artinian algebra $A$ over a field $K$ is said to have the weak Lefschetz property if there is a linear form $\ell \in A$ such that the multiplication map $\times \ell : [A]_i \rightarrow [A]_{i+1}$ has maximal rank for all $i$ (i.e., it is injective or surjective). The algebra $A$ has the strong Lefschetz property if $\times \ell^d : [A]_i \rightarrow [A]_{i+d}$ has maximal rank for all $i$ and $d$. The names are motivated by the conclusion of the Hard Lefschetz Theorem on the cohomology ring of a compact Kähler manifold. Many algebras are expected to have the Lefschetz properties. However, deciding this problem is often very challenging.

The presence of the weak Lefschetz property has profound consequences for an algebra (see [19]). For example, Stanley used this in his contribution [37] towards the proof of the so-called $g$-Theorem that characterizes the face vectors of simplicial polytopes. It has been a longstanding conjecture whether this characterization extends to the face vectors of all triangulations of a sphere. In fact, this would be one of the consequences if one can show the so-called algebraic $g$-Conjecture, which posits that a certain algebra has the strong Lefschetz property (see [31] and [32]). Although there has been a flurry of papers studying the Lefschetz properties in the last decade (see, e.g., [2, 3, 4, 5, 13, 17, 18, 21, 22, 23, 25, 28]), we currently seem far from being able to decide the above conjectures. Indeed, the need for new methods has led us to consider lozenge tilings, perfect matchings, and families of non-intersecting lattice paths. We use this approach to establish new results about the presence or the absence of the weak Lefschetz property for quotients of a polynomial ring $R$ in three variables. This is the first open case as any Artinian quotient of a polynomial ring in two variables has even the strong Lefschetz property in characteristic zero [19].

If $I$ is a monomial ideal, then $R/I$ is Artinian of type one if and only if $I$ is generated by
the powers of the three variables. It is well-known that in this case $R/I$ has the Lefschetz
properties if the base field has characteristic zero (see [36, 35, 38, 12]). We extent this result
by providing a version for base fields of arbitrary characteristic (see Theorem 6.2).

Monomial algebras $R/I$ of type two were considered in the recent memoir [1]. One of
its main results says that, in characteristic zero, these algebras have the weak Lefschetz
property, provided they are also level. Examples show that this may fail if one drops the
level assumption or if $K$ has positive characteristic. However, the intricate proof in the level
case of [1, Theorem 6.2] does not give any insight when such failures occur. We resolve this
by completely classifying all type two algebras that have the weak Lefschetz property if the
characteristic is zero or large enough (see Theorem 7.2 and Proposition 7.9).

The structure of this paper is as follows. In Section 2, we recall or derive some general
results about the presence of the weak Lefschetz property. In Section 3, we describe a
key relation between a monomial ideal and a triangular region, a certain planar region, as
introduced in [11]. In Section 4, we consider signed lozenge tilings of a triangular region,
using two a priori different signs. We show that both signs lead to enumerations of signed
lozenge tilings that completely control the presence of the weak Lefschetz property, regardless
of the characteristic of the base field. In Section 5 we work out some enumerations explicitly.
We describe some rather general techniques and then illustrate them by evaluation certain
determinants. Sections 2 to 5 constitute our combinatorial approach towards the Lefschetz
properties of monomial ideals. We then apply it to study monomial algebras of type one and
two in Section 6 and Section 7, respectively.

2. The weak Lefschetz property

There are some general results that are helpful in order to determine the presence or
absence of the weak Lefschetz property. We recall or derive these tools here.

Throughout this paper, let $R = K[x_1, \ldots, x_n]$ be a standard graded polynomial ring in $n$
variables over a field $K$. Furthermore, all $R$-modules are assumed to be finitely generated
and graded. The Hilbert function of an $R$-module $M$ is the function $h_M : \mathbb{Z} \to \mathbb{Z}$ defined by
$h_M(j) = \dim_K [M]_j$. Let $M$ be an Artinian $R$-module. The socle of $M$, denoted $soc\ M$, is
the annihilator of $m = (x_1, \ldots, x_n)$, the homogeneous maximal ideal of $R$, that is, $soc\ M = \{y \in M \mid y \cdot m = 0\}$. The type of $M$ is the $K$-dimension of $soc\ M$. The socle degree
or Castelnuovo-Mumford regularity of $M$ is the maximum degree of a non-zero element in
soc $M$. The module $M$ is said to be level if all socle generators have the same degree, i.e.,
its socle is concentrated in one degree.

Alternatively, assume that the minimal free resolution of $M$ over $R$ ends with a free module
$\bigoplus_{i=1}^m R(-t_i)$, where $t_1 \leq \cdots \leq t_m$ for all $i$. Then $M$ has $m$ socle generators with degrees
$t_1 - n, \ldots, t_m - n$. Thus, $M$ is level if and only if $m = 1$.

It was observed in [27, Proposition 2.1(a)] that once multiplication by a general linear
form on a quotient of $R$ is surjective, then it remains surjective. This can be extended to
modules.

Lemma 2.1. Let $M$ be a graded $R$-module such that the degrees of its minimal generators
are at most $d$. Let $\ell \in R$ be a linear form. If the map $\times \ell : [M]_{d-1} \to [M]_d$ is surjective, then
the map $\times \ell : [M]_{j-1} \to [M]_j$ is surjective for all $j \geq d$. 
**The Weak Lefschetz Property for Monomial Ideals of Small Type**

**Proof.** Consider the exact sequence \([M]_{d-1} \xrightarrow{\times \ell} [M]_d \rightarrow [M/\ell M]_d \rightarrow 0\). Notice the first map is surjective if and only if \([M/\ell M]_d = 0\). Thus, the assumption gives \([M/\ell M]_d = 0\). Hence \([M/\ell M]_{j+1}\) is zero for all \(j \geq d\) because \(M\) does not have minimal generators having a degree greater than \(d\), by assumption.

As a consequence, we note a slight generalization of [27, Proposition 2.1(b)], which considers the case of level algebras.

**Corollary 2.2.** Let \(M\) be an Artinian graded \(R\)-module such that the degrees of its non-trivial socle elements are at least \(\geq d - 1\). Let \(\ell \in R\) be a linear form. If the map \(\times \ell : [M]_{d-1} \rightarrow [M]_d\) is injective, then the map \(\times \ell : [M]_{j-1} \rightarrow [M]_j\) is injective for all \(j \leq d\).

**Proof.** Recall that the \(K\)-dual of \(M\) is \(M^\vee = \text{Hom}_K(M, K)\). Then \(\times \ell : [M]_{j-1} \rightarrow [M]_j\) is injective if and only if the map \(\times \ell : [M^\vee]_{-j} \rightarrow [M^\vee]_{-j+1}\) is surjective. The assumption on the socle of \(M\) means that the degrees of the minimal generators of \(M^\vee\) are at most \(-d+1\). Thus, we conclude by Lemma 2.1.

The above observations imply that to decide the presence of the weak Lefschetz property we need only check near a “peak” of the Hilbert function.

**Proposition 2.3.** Let \(A \neq 0\) be an Artinian standard graded \(K\)-algebra. Let \(\ell\) be a general linear form. Then there are the following facts:

(i) Let \(d\) be the smallest integer such that \(h_A(d-1) > h_A(d)\). If \(A\) has a non-zero socle element of degree less than \(d - 1\), then \(A\) does not have the weak Lefschetz property.

(ii) Let \(d\) be the largest integer such that \(h_A(d-2) < h_A(d-1)\). If \(A\) has the weak Lefschetz property, then

(a) \(\times \ell : [A]_{d-2} \rightarrow [A]_{d-1}\) is injective,
(b) \(\times \ell : [A]_{d-1} \rightarrow [A]_d\) is surjective, and
(c) \(A\) has no socle generators of degree less than \(d - 1\).

(iii) Let \(d \geq 0\) be an integer such that \(A\) has the following three properties:

(a) \(\times \ell : [A]_{d-2} \rightarrow [A]_{d-1}\) is injective,
(b) \(\times \ell : [A]_{d-1} \rightarrow [A]_d\) is surjective, and
(c) \(A\) has no socle generators of degree less than \(d - 2\).

Then \(A\) has the weak Lefschetz property.

**Proof.** Suppose in case (i) \(A\) has a socle element \(y \neq 0\) of degree \(e < d - 1\). Then \(\ell y = 0\), and so the map \(\times \ell : [A]_e \rightarrow [A]_{e+1}\) is not injective. Moreover, since \(e < d - 1\) we have \(h_{R/I}(e) \leq h_{R/I}(e+1)\). Hence, the map \(\times \ell : [A]_e \rightarrow [A]_{e+1}\) does not have maximal rank. This proves claim (i).

For showing (ii), suppose \(A\) has the weak Lefschetz property. Then, by its definition, \(A\) satisfies (ii)(a) and (ii)(b) because \(h_A(d-1) \geq h_A(d)\). Assume (ii)(c) is not true, that is, \(A\) has a socle element \(y \neq 0\) of degree \(e < d - 1\). Then the map \(\times \ell : [A]_e \rightarrow [A]_{e+1}\) is not injective. Since \(A\) has the weak Lefschetz property, this implies \(h_A(e) > h_A(e+1)\). Hence the assumption on \(d\) gives \(e \leq d - 3\). However, this means that the Hilbert function of \(A\) is not unimodal. This is impossible if \(A\) has the weak Lefschetz property (see [19]).

Finally, we prove (iii). Corollary 2.2 and Assumptions (iii)(a), and (iii)(c) imply that the map \(\times \ell : [A]_{i-2} \rightarrow [A]_{i-1}\) is injective if \(i \leq d\). Furthermore, using (iii)(b) and Lemma 2.1 we see that \(\times \ell : [A]_{i-1} \rightarrow [A]_i\) is surjective if \(i \geq d\). Thus, \(A\) has the weak Lefschetz property.
If the Hilbert function has two peaks in consecutive degrees, a situation to which we refer as “twin peaks,” the above arguments give the following result.

**Corollary 2.4.** Let $A$ be an Artinian standard graded $K$-algebra, and let $\ell$ be a general linear form. Suppose there is an integer $d$ such that $0 \neq h_A(d-1) = h_A(d)$ and $A$ has no socle elements of degree less than $d-1$. Then $A$ has the weak Lefschetz property if and only if $\times \ell : [A]_{d-1} \to [A]_d$ is bijective.

The following easy, but useful observation is essentially the content of [27, Proposition 2.2].

**Proposition 2.5.** Let $A = R/I$ be an Artinian $K$-algebra, where $I$ is generated by monomials and $K$ is an infinite field. Let $d$ and $e > 0$ be integers. Then the following conditions are equivalent:

(i) The multiplication map $\times \ell^e : [A]_{d-e} \to [A]_d$ has maximal rank, where $\ell \in R$ is a general linear form.

(ii) The multiplication map $\times (x_1 + \cdots + x_n)^e : [A]_{d-e} \to [A]_d$ has maximal rank.

**Proof.** For the convenience of the reader we recall the argument. Let $\ell = a_1x_1 + + a_rx_r \in R$ be a general linear form. Thus, we may assume that each coefficient $a_i$ is not zero. Rescaling the variables $x_i$ such that $\ell$ becomes $x_1 + \cdots + x_n$ provides an automorphism of $R$ that maps $I$ onto $I$. 

Hence, for monomial algebras, it is enough to decide whether the sum of the variables is a Lefschetz element. As a consequence, the presence of the weak Lefschetz property in characteristic zero is equivalent to the presence of the weak Lefschetz property in some (actually, almost every) positive characteristic.

Recall that a **maximal minor** of a matrix $B$ is the determinant of a maximal square sub-matrix of $B$.

**Corollary 2.6.** Let $A$ be an Artinian monomial $K$-algebra, where $K$ is infinite. Then the following conditions are equivalent:

(i) $A$ has the weak Lefschetz property in characteristic zero.

(ii) $A$ has the weak Lefschetz property in some positive characteristic.

(iii) $A$ has the weak Lefschetz property in every sufficiently large positive characteristic.

**Proof.** Let $\ell = x_0 + \cdots + x_n$. By Proposition 2.5, $A$ has the weak Lefschetz property if, for each integer $d$, the map $\times \ell : [A]_{d-1} \to [A]_d$ has maximal rank. As $A$ is Artinian, there are only finitely many non-zero maps to be checked. Fixing monomial bases for all non-trivial components $[A]_j$, the mentioned multiplication maps are described by zero-one matrices.

Suppose $A$ has the weak Lefschetz property in some characteristic $q \geq 0$. Then for each of the finitely many matrices above, there exists a maximal minor that is non-zero in $K$, hence non-zero as an integer. The finitely many non-zero maximal minors, considered as integers, have finitely many prime divisors. Hence, there are only finitely many prime numbers, which divide one of these minors. If the characteristic of $K$ does not belong to this set of prime numbers, then $A$ has the weak Lefschetz property.

We conclude this subsection by noting that any Artinian ideal in two variables has the weak Lefschetz property. This was first proven for characteristic zero in [19, Proposition 4.4] and then for arbitrary characteristic in [30, Corollary 7], though it was not specifically stated therein (see [23, Remark 2.6]). We provide a brief, direct argument here.
Proposition 2.7. Let $R = K[x, y]$, where $K$ is an infinite field of arbitrary characteristic. Then every Artinian graded algebra $R/I$ has the weak Lefschetz property.

Proof. Let $\ell \in R$ be a general linear form, and put $s = \min\{j \in \mathbb{Z} \mid [I]_j \neq 0\}$. As $[R]_i = [R/I]_i$ for $i < s$ and multiplication by $\ell$ on $R$ is injective, we see that $[R/I]_{i-1} \to [R/I]_i$ is injective if $i < s$. Moreover, since $R/(I, \ell) \cong K[x]/(x^s)$ and $[K[x]/(x^s)]_i = 0$ for $i \geq s$, the map $[R/I]_{i-1} \to [R/I]_i$ has a trivial cokernel if $i \geq s$, that is, the map is surjective if $i \geq s$. Hence $R/I$ has the weak Lefschetz property. \hfill $\square$

Due to this fact, the problem of deciding whether a quotient of $R$ has the weak Lefschetz property is only interesting if $n \geq 3$. In this paper we focus on the case $n = 3$, which provides intriguing questions and connections to challenging problems in combinatorics as we are going to show.

3. Triangular regions

From now we consider polynomial rings in three variables. For simplicity, we write $R = K[x, y, z]$. In this section, we begin developing a combinatorial approach for deciding the presence of the weak Lefschetz property for $R/I$, where $I$ is a monomial ideal. To this end we associate to $I$ a planar region and consider its tilings by lozenges.

3.1. Triangular regions and monomial ideals.

Let $d \geq 1$ be an integer. Consider an equilateral triangle of side length $d$ that is composed of $\binom{d}{2}$ downward-pointing ($\bigtriangleup$) and $\binom{d+1}{2}$ upward-pointing ($\triangle$) equilateral unit triangles. We label the downward- and upward-pointing unit triangles by the monomials in $[R]_{d-2}$ and $[R]_{d-1}$, respectively, as follows: place $x^{d-1}$ at the top, $y^{d-1}$ at the bottom-left, and $z^{d-1}$ at the bottom-right, and continue labeling such that, for each pair of an upward- and a downward-pointing triangle that share an edge, the label of the upward-pointing triangle is obtained from the label of the downward-pointing triangle by multiplying with a variable. The resulting labeled triangular region is the triangular region (of $R$) in degree $d$ and is denoted $T_d$. See Figure 3.1(i) for an illustration.

![Figure 3.1](image_url)

**Figure 3.1.** A triangular region with respect to $R$ and with respect to $R/I$.

Throughout this manuscript we order the monomials of $R$ by using the graded reverse-lexicographic order, that is, $x^ay^bz^c > x^py^qz^r$ if either $a+b+c > p+q+r$ or $a+b+c = p+q+r$ and the last non-zero entry in $(a-p, b-q, c-r)$ is negative. For example, in degree 3,

$$x^3 > x^2y > xy^2 > y^3 > x^2z > xyz > y^2z > xz^2 > yz^2 > z^3.$$
Thus in $T_d$, see Figure 3.1(i), the upward-pointing triangles are ordered starting at the top and moving down-left in lines parallel to the upper-left edge.

We generalize this construction to quotients by monomial ideals. Let $I$ be any monomial ideal of $R$. The triangular region (of $R/I$) in degree $d$, denoted by $T_d(I)$, is the part of $T_d$ that is obtained after removing the triangles labeled by monomials in $I$. Note that the labels of the downward- and upward-pointing triangles in $T_d(I)$ form $K$-bases of $[R/I]_{d-2}$ and $[R/I]_{d-1}$, respectively. It is sometimes more convenient to illustrate triangular regions with the removed triangles darkly shaded instead of being removed; both illustration methods will be used throughout this manuscript. See Figure 3.1(ii) for an example.

Notice that the regions missing from $T_d$ in $T_d(I)$ can be viewed as a union of (possibly overlapping) upward-pointing triangles of various side lengths that include the upward- and downward-pointing triangles inside them. Each of these upward-pointing triangles corresponds to a minimal generator of $I$ that has, necessarily, degree at most $d - 1$. We can alternatively construct $T_d(I)$ from $T_d$ by removing, for each minimal generator $x^a y^b z^c$ of $I$ of degree at most $d - 1$, the puncture associated to $x^a y^b z^c$ which is an upward-pointing equilateral triangle of side length $d - (a + b + c)$ located $a$ triangles from the bottom, $b$ triangles from the upper-right edge, and $c$ triangles from the upper-left edge. See Figure 3.2 for an example. We call $d - (a + b + c)$ the side length of the puncture associated to $x^a y^b z^c$, regardless of possible overlaps with other punctures in $T_d(I)$.

We say that two punctures overlap if they share at least an edge. Two punctures are said to be touching if they share precisely a vertex.

3.2. Tilings with lozenges.

Now we consider tilings of a triangular region by lozenges. A lozenge is a union of two unit equilateral triangles glued together along a shared edge, i.e., a rhombus with unit side lengths and angles of $60^\circ$ and $120^\circ$. Lozenges are also called calissons and diamonds in the literature.

Fix a positive integer $d$ and consider the triangular region $T_d$ as a union of unit triangles. Thus a subregion $T \subset T_d$ is a subset of such triangles. We retain their labels. We say that a subregion $T$ is $\nabla$-heavy, $\triangle$-heavy, or balanced if there are more downward pointing than upward pointing triangles or less, or if their numbers are the same, respectively. A subregion is tileable if either it is empty or there exists a tiling of the region by lozenges such that every triangle is part of exactly one lozenge. See Figure 3.3 for an example.
Let $T \subset \mathcal{T}_d$ be any subregion. Given a monomial $x^ay^bz^c$ with degree less than $d$, the monomial subregion of $T$ associated to $x^ay^bz^c$ is the part of $T$ contained in the triangle $a$ units from the bottom edge, $b$ units from the upper-right edge, and $c$ units from the upper-left edge. In other words, this monomial subregion consists of the triangles that are in $T$ and in the puncture associated to the monomial $x^ay^bz^c$. See Figure 3.4 for an illustration.

Notice that a tileable subregion is necessarily balanced. In fact, a balanced triangular region $T_d(I)$ is tileable if and only if it has no $\bigtriangleup$-heavy monomial subregions (see [11, Theorem 2.2]). The argument uses the following result, which we record for a later application.

**Lemma 3.1** ([11, Lemma 2.1]). Let $T \subset \mathcal{T}_d$ be any subregion. If the monomial subregion $U$ of $T$ associated to $x^ay^bz^c$ is tileable, then $T$ is tileable if and only if $T \setminus U$ is tileable. Moreover, each tiling of $T$ is obtained by combining a tiling of $T \setminus U$ and a tiling of $U$.

Now we introduce two enumerations of signed lozenge tilings, using perfect matchings and families of lattice paths, and relate these enumerations to the presence of the weak Lefschetz property.

### 4. Enumerations deciding the weak Lefschetz property

Now we introduce two enumerations of signed lozenge tilings, using perfect matchings and families of lattice paths, and relate these enumerations to the presence of the weak Lefschetz property.

**4.1. Perfect matchings.** Let $T \subset \mathcal{T}_d$ be any subregion. As above, we consider $T$ as a union of unit triangles. Following [11], we associate to $T$ a bipartite graph. This construction has also been considered in, e.g., [6], [7], and [15]. First, place a vertex at the center of each triangle. Let $B$ be the set of centers of the downward-pointing triangles, and let $W$ be the set of centers of the upward-pointing triangles. The bipartite graph associated to $T$ is the bipartite graph $G(T)$ on the vertex set $B \cup W$ that has an edge between vertices $B_i \in B$...
and \( W_j \in W \) if the corresponding upward- and downward-pointing triangle share are edge. In other words, edges of \( G(T) \) connect vertices of adjacent triangles. See Figure 4.1(i).

\begin{figure}[h]
\centering
\begin{tabular}{ccc}
(i) & (ii) & (iii) \\
\includegraphics[width=0.3\textwidth]{figure41i.png} & \includegraphics[width=0.3\textwidth]{figure41ii.png} & \includegraphics[width=0.3\textwidth]{figure41iii.png}
\end{tabular}
\caption{Given the tiling \( \tau \) in Figure 3.3(ii) of \( T \), we construct the perfect matching \( \pi \) of the bipartite graph \( G(T) \) associated to \( \tau \).}
\end{figure}

Using the above ordering of the vertices, we define the bi-adjacency matrix of \( T \) as the bi-adjacency matrix \( Z(T) := Z(G(T)) \) of the graph \( G(T) \). It is the zero-one matrix \( Z(T) \) of size \( #B \times #W \) with entries \( Z(T)_{ij} \) defined by

\[ Z(T)_{ij} = \begin{cases} 1 & \text{if } (B_i, W_j) \text{ is an edge of } G(T) \\ 0 & \text{otherwise.} \end{cases} \]

It is a square matrix if and only if the region \( T \) is balanced.

A perfect matching of a graph \( G \) is a set of pairwise non-adjacent edges of \( G \) such that each vertex is matched. There is well-known bijection between lozenge tilings of a balanced subregion \( T \) and perfect matchings of \( G(T) \). A lozenge tiling \( \tau \) is transformed in to a perfect matching \( \pi \) by overlaying the triangular region \( T \) on the bipartite graph \( G(T) \) and selecting the edges of the graph that the lozenges of \( \tau \) cover. See Figures 4.1. Using this bijection, it follows that the permanent of the bi-adjacency matrix enumerates the unsigned tilings of the region.

Proposition 4.1. If \( T \subset T_d \) is a non-empty balanced subregion, then the lozenge tilings of \( T \) are enumerated by \( \text{perm} \ Z(T) \).

Considering a perfect matching \( \pi \) as a permutation on \( #\triangle(T) = # \Box (T) \) letters, it is natural to assign a sign to each lozenge tiling using the signature of the permutation \( \pi \).

Definition 4.2. Let \( T \subset T_d \) be a non-empty balanced subregion. Then we define the perfect matching sign of a lozenge tiling \( \tau \) of \( T \) as \( \text{msgn} \ \tau := \text{sgn} \ \pi \), where \( \pi \in \mathfrak{S}_{#\triangle(T)} \) is the perfect matching determined by \( \tau \).

Thus the perfect matching signed tilings of a region are enumerated by the determinant of a bi-adjacency matrix.

Theorem 4.3 (\cite{Institute}, Theorem 3.5). If \( T \subset T_d \) is a non-empty balanced subregion, then the perfect matching signed lozenge tilings of \( T \) are enumerated by \( |\det Z(T)| \), that is,

\[ \sum_{\tau \text{ tiling of } T} \text{msgn} \ \tau = |\det Z(T)|. \]
We recursively define a puncture of $T \subset T_d$ to be a non-floating puncture if it touches the boundary of $T_d$ or if it overlaps or touches a non-floating puncture of $T$. Otherwise we call a puncture a floating puncture. For example, the region $T$ in Figure 3.3 has three non-floating punctures (in the corners) and three floating punctures, two of them are overlapping and have side length two.

In the case, where the floating punctures all have even side lengths, the sign $\text{sgn} \tau$ is constant.

**Proposition 4.4** ([11, Corollary 4.7]). If $T \subset T_d$ is a tileable triangular region such that all floating punctures of $T$ have an even side length, then every lozenge tiling of $T$ has the same perfect matching sign, and so $Z(T) = |\det Z(T)|$.

This result applies in particular to tileable, simply connected triangular regions.

We now relate the above results about triangular regions associated to a monomial ideal $I$ to the weak Lefschetz property of $R/I$. The key is an alternative description of the bi-adjacency matrix $Z(T)$ to $T = T_d(I)$ that involves multiplication by $\ell = x + y + z$.

**Proposition 4.5.** Let $I$ be a monomial ideal in $R = K[x,y,z]$, and let $\ell = x + y + z$. Fix an integer $d$ and consider the multiplication map $\times(x+y+z) : [R/I]_{d-2} \to [R/I]_{d-1}$. Let $M(d)$ be the matrix to this linear map with respect to the monomial bases of $[R/I]_{d-2}$ and $[R/I]_{d-1}$ in reverse-lexicographic order. Then the transpose of $M(d)$ is the bi-adjacency matrix $Z(T_d(I))$.

**Proof.** Set $s = h_{R/I}(d-2)$ and $t = h_{R/I}(d-1)$, and let $\{m_1, \ldots, m_s\}$ and $\{n_1, \ldots, n_t\}$ be the distinct monomials in $[R]_{d-2} \setminus I$ and $[R]_{d-1} \setminus I$, respectively, listed in reverse-lexicographic order. Then the matrix $M(d)$ is a $t \times s$ matrix. Its column $j$ is the coordinate vector of $\ell m_j = xm_i + ym_i + zm_i$ modulo $I$ with respect to the chosen basis of $[R/I]_{d-1}$. In particular, the entry in column $j$ and row $i$ is 1 if and only if $n_i$ is a multiple of $m_j$.

Recall that the rows and columns of $Z(T_d(I))$ are indexed by the downward- and upward-pointing unit triangles, respectively. These triangles are labeled by the monomials in $[R]_{d-2} \setminus I$ and $[R]_{d-1} \setminus I$, respectively. Since the label of an upward-pointing triangle is a multiple of the label of a downward-pointing triangle if and only if the triangles are adjacent, it follows that $Z(T_d(I)) = M(d)^T$. \qed

For ease of reference, we record the following consequence.

**Corollary 4.6.** Let $I$ be a monomial ideal in $R = K[x,y,z]$. Then the multiplication map $\times(x+y+z) : [R/I]_{d-2} \to [R/I]_{d-1}$ has maximal rank if and only if the matrix $Z(T_d(I))$ has maximal rank.

Combined with Proposition 2.5 we get a criterion for the presence of the weak Lefschetz property.

**Corollary 4.7.** Let $I$ be an Artinian monomial ideal in $R = K[x,y,z]$, where $K$ is infinite. Then $R/I$ has the weak Lefschetz property if and only if, for each positive integer $d$, the matrix $Z(T_d(I))$ has maximal rank.

Assuming large enough socle degrees, it is enough to consider at most two explicit matrices to check for the weak Lefschetz property.

**Corollary 4.8.** Let $I$ be an Artinian monomial ideal in $R = K[x,y,z]$, where $K$ is infinite, and suppose the degrees of the socle generators of $R/I$ are at least $d - 2$. Then:
Proof. By Proposition 2.5 it is enough to check whether
\[10 \ D. \ COOK \ II \ AND \ U. \ NAGEL\]
if and only if \(\det Z(T_d(I))\) is not zero in \(K\).

(ii) If \(h_{R/I}(d-2) < h_{R/I}(d-1)\) and \(h_{R/I}(d-1) > h_{R/I}(d)\), then \(R/I\) has the weak
Lefschetz property if and only if \(Z(T_d(I))\) and \(Z(T_{d+1}(I))\) both have a maximal minor
that is not zero in \(K\).

Proof. By Proposition 2.5 it is enough to check whether \(\ell = x + y + z\) is a Lefschetz
element of \(R/I\). Hence, the result follows by combining Corollary 4.6 and Proposition 2.3
and Corollary 2.4 respectively.

In the case, where the region \(T_d(I)\) is balanced, we interpreted the determinant of \(Z(T_d(I))\)
as the enumeration of signed perfect matchings on the bipartite graph \(G(T_d(I))\). This is also
useful for non-balanced regions.

**Remark 4.9.** For any region \(T_d(I)\), we interpret a maximal minor of \(Z(T_d(I))\) as enumeration
for a region obtained by removing unit triangles from \(T_d(I)\), since the rows and columns
of \(Z(T_d(I))\) are indexed by the triangles of \(T_d(I)\). More precisely, let \(T = T_d(I)\) be a \(\triangledown\)-heavy
triangular region with \(k\) more downward-pointing triangles than upward-pointing triangles.
Abusing notation slightly, we define a maximal minor of \(T\) to be a balanced subregion \(U\)
of \(T\) that is obtained by removing \(k\) downward-pointing triangles from \(T\). Similarly, if \(T\) is
\(\triangle\)-heavy, then we remove only upward-pointing triangles to get a maximal minor.

Clearly, if \(U\) is a maximal minor of \(T\), then \(\det Z(U)\) is indeed a maximal minor of \(Z(T)\).
Thus, \(Z(T)\) has maximal rank if and only if there is a maximal minor \(U\) of \(T\) such that \(Z(U)\)
has maximal rank.

**Example 4.10.** Let \(I = (x^4, y^4, z^4, x^2z^2)\). Then the Hilbert function of \(R/I\), evaluated
between degrees 0 and 7, is \((1, 3, 6, 10, 11, 9, 6, 2)\), and \(R/I\) is level with socle degree 7.
Hence, by Corollary 4.8, \(R/I\) has the weak Lefschetz property if and only if \(Z(T_5(I))\) and
\(Z(T_6(I))\) both have a maximal minor of maximal rank.

\[\begin{align*}
  T_5(I) & \quad U & \quad U' & \quad T_6(I) & \quad U'' \\
  (i) \ \det Z(U) = 0 \ \text{and} \ |\det Z(U')| = 4 \\
  (ii) \ |\det Z(U'')| = 1
\end{align*}\]

**Figure 4.2.** Examples of maximal minors of \(T_d(I)\), where \(I = (x^4, y^4, z^4, x^2z^2)\).

Since \(h_{R/I}(3) = 10 < h_{R/I}(4) = 11\), we need to remove 1 upward-pointing triangle from
\(T_5(I)\) to get a maximal minor of \(T_5(I)\); see Figure 4.2(i) for a pair of examples. There are \((11)\) = 11 maximal minors, and these have signed enumerations with magnitudes 0, 4, and
8. Thus multiplication from degree 3 to degree 4 fails injectivity exactly if the characteristic
of \(K\) is 2.

Furthermore, since \(h_{R/I}(4) = 11 > h_{R/I}(5) = 9\), we need to remove 2 downward-pointing
triangles from \(T_6(I)\) to get a maximal minor of \(T_6(I)\); see Figure 4.2(ii) for an example.
There are \((11)\) = 55 maximal minors, and these have signed enumerations with magnitudes
0, 1, 2, 3, 5, and 8. Thus multiplication from degree 4 to degree 5 is always surjective (choose
the maximal minor whose signed enumeration is 1).
Hence, we conclude that \( R/I \) has the weak Lefschetz property if and only if the characteristic of the base field is not 2.

4.2. Non-intersecting lattice paths. Following [3] Section 5] (similarly, [16] Section 2) we associate to \( T \subset T_d \) a finite set \( L(T) \) that can be identified with a subset of the lattice \( \mathbb{Z}^2 \). Abusing notation, we refer to \( L(T) \) as a sub-lattice of \( \mathbb{Z}^2 \). We then employ a relation between lozenge tilings and families of non-intersecting lattice paths (see [14] for details).

To construct \( L(T) \), place a vertex at the midpoint of the edge of each triangle of \( T \) that is parallel to the upper-left boundary of the triangle \( T_d \). We use the monomial label of the upward-pointing triangle on whose edge the midpoint is located to specify this vertex of \( L(T) \). In order to construct paths on \( L(T) \), we think of rightward motion parallel to the bottom edge of \( T_d \) as “horizontal” and downward motion parallel to the upper-right edge of \( T_d \) as “vertical” motion. Thus, orthogonalizing \( L(T) \) with respect to these motions moves the vertex associated to a monomial \( x^ay^bz^d \) in \( L(T) \) to the point \((d - 1 - b, a)\) in \( \mathbb{Z}^2 \) (see Figure 4.3).

We next single out special vertices of \( L(T) \). Label the vertices of \( L(T) \) that are only on upward-pointing triangles in \( T \), from smallest to largest in the reverse-lexicographic order, as \( A_1, \ldots, A_m \). Similarly, label the vertices of \( L(T) \) that are only on downward-pointing triangles in \( T \), again from smallest to largest in the reverse-lexicographic order, as \( E_1, \ldots, E_n \). See Figure 4.3(i). Note that there are an equal number of vertices \( A_1, \ldots, A_m \) and \( E_1, \ldots, E_n \) if and only if the region \( T \) is balanced.

A lattice path in a lattice \( L \subset \mathbb{Z}^2 \) is a finite sequence of vertices of \( L \) so that all single steps move either to the right or down. Given any vertices \( A, E \in \mathbb{Z}^2 \), the number of lattice paths in \( \mathbb{Z}^2 \) from \( A \) to \( E \) is a binomial coefficient. In fact, if \( A \) and \( E \) have coordinates \((u, v), (x, y) \in \mathbb{Z}^2 \), there are \((x-u+v-y) \) lattice paths from \( A \) to \( E \) in \( \mathbb{Z}^2 \).

Using the above identification of \( L(T) \) as a sub-lattice of \( \mathbb{Z}^2 \), a lattice path in \( L(T) \) is a finite sequence of vertices of \( L(T) \) so that all single steps move either to the East or to the Southeast. The lattice path matrix of \( T \) is the \( m \times n \) matrix \( N(T) \) with entries \( N(T)_{(i,j)} \) defined by

\[
N(T)_{(i,j)} = \# \text{lattice paths in } \mathbb{Z}^2 \text{ from } A_i \text{ to } E_j.
\]

Thus, the entries of \( N(T) \) are binomial coefficients.

Next we consider several lattice paths simultaneously. A family of non-intersecting lattice paths is a finite collection of lattice paths such that no two lattice paths have any points in common. If \( T \) is balanced, so \( m = n \), there is a well-known bijection between lozenge tilings of \( T \) and families of non-intersecting lattice paths from \( A_1, \ldots, A_m \) to \( E_1, \ldots, E_m \); see, e.g., the survey [33]. Let \( \tau \) be a lozenge tiling of \( T \). Using the lozenges of \( \tau \) as a guide, we connect each pair of vertices of \( L(T) \) that occur on a single lozenge. This generates the family of non-intersecting lattice paths \( \Lambda \) of \( L(T) \) corresponding to \( \tau \). See Figures 4.3(ii) and (iii).

Consider now a family \( \Lambda \) of \( m \) non-intersecting lattice paths in \( L(T) \) from \( A_1, \ldots, A_m \) to \( E_1, \ldots, E_m \). Then \( \Lambda \) determines a permutation \( \lambda \in \mathfrak{S}_m \) such that the path in \( \Lambda \) that begins at \( A_i \) ends at \( E_{\lambda(i)} \). Using the signature of \( \lambda \) gives another way for assigning a sign to a lozenge tiling of \( T \).

Definition 4.11. Let \( T \subset T_d \) be a non-empty balanced subregion as above, and let \( \tau \) be a lozenge tiling of \( T \). Then we define the lattice path sign of \( \tau \) as \( \text{lpsgn } \tau := \text{sgn } \lambda \), where \( \lambda \in \mathfrak{S}_m \) is the permutation such that, for each \( i \), the lattice path determined by \( \tau \) that starts at \( A_i \) ends at \( E_{\lambda(i)} \).
By now we described two signs of a lozenge tiling, one using perfect matchings and one using lattice paths. In fact, it is shown in [11] that these two signs are essentially the same. Thus we can enumerate the signed tilings of a triangular region $T$ by using its lattice path matrix $N(T)$ or its bi-adjacency matrix $Z(T)$.

**Theorem 4.12 ([11] Theorems 3.9 and 4.6).** If $T \subset T_d$ is a non-empty balanced triangular region, then the perfect matching signed lozenge tilings and the lattice path signed lozenge tilings of $T$ are both enumerated by $|\det Z(T)| = |\det N(T)|$, that is,

$$\sum_{\tau \text{ tiling of } T} \text{msgn } \tau = |\det Z(T)| = |\det N(T)| = \sum_{\tau \text{ tiling of } T} \text{lpsgn } \tau.$$  

We now show that the lattice path matrix $N(T_d(I))$ is also relevant for studying the weak Lefschetz property of $R/I$. If $N(T_d(I))$ is a square matrix, then this follows from the results in Subsection 4.1 and Theorem 4.12. However, this matrix is also relevant, even if it is not square. In fact, $N(T_d(I))$ is related to the cokernel of multiplication by $\ell = x + y + z$ on $R/I$.

**Proposition 4.13.** Let $I$ be a monomial ideal of $R = K[x, y, z]$. Fix an integer $d$ and set $N = N(T_d(I))$. Then $\dim_K [R/(I, x + y + z)]_{d-1} = \dim_K \ker N^T$.

**Proof.** Note that $R/(I, x + y + z)$ is isomorphic to $[S/J]_{d-1}$, where $S = K[x, y]$ and $J$ is the ideal generated by the generators of $I$ with $x + y$ substituted for $z$.

We now describe a matrix whose rank equals $\dim_K [J]_{d-1}$. Define an integer $a$ as the least power of $x$ in $I$ that is less than $d$, and set $a := d$ if no such power exist. Similarly, define an integer $b \leq d$ using powers of $y$ in $I$. Let $G_1$ and $G_3$ be the sets of monomials in $x^a[S]_{d-1-a}$ and $y^b[S]_{d-1-b}$, respectively. Furthermore, let $G_2$ be the set consisting of the polynomials $x^p y^{d-1-p-e}(x + y)^e \in [J]_{d-1}$ such that $x^p y^e$ is a minimal generator of $I$, where $e > 0$, $i \leq p$, and $j \leq d - 1 - p - e$. Thus, replacing $x + y$ by $z$, each element of $G_2$ corresponds to a monomial $x^p y^{d-1-p-e}z^e \in [I]_{d-1}$. Order the elements of $G_2$ by using the reverse-lexicographic order of the corresponding monomials in $[I]_{d-1}$, from smallest to largest. Similarly, order the monomials in $G_1$ and $G_3$ reverse-lexicographically, from smallest to largest. Note that $G_1 \cup G_2 \cup G_3$ is a generating set for the vector space $[J]_{d-1}$. The coordinate vector of a polynomial in $[S]_{d-1}$ with respect to the monomial basis of $[S]_{d-1}$ has as entries the coefficients of the monomials in $[S]_{d-1}$. Order this basis again reverse-lexicographically from smallest to largest. Now let $M$ be the matrix whose column vectors

![Diagram](image-url)
are the coordinate vectors of the polynomials in $G_1, G_2,$ and $G_3$, listed in this order. Then 
\[ \dim_K [J]_{d-1} = \text{rank } M \] because $G$ generates $[J]_{d-1}$. Finally, consider the lattice path matrix $N = N(T_d(I))$. Its rows and columns are indexed by the starting and end points of lattice paths, respectively. Fix a starting point $A_i$ and an end point $E_j$. The monomial label of $A_i$ is of the form $x^s y^{d-1-s}$, where $x^s y^{d-1-s} \notin I$. Thus, the orthogonalized coordinates of $A_i$ are $(s, s)$. The monomial label of the end point $E_j$ is of the form $x^p y^{d-1-p-e} z^e$, where $x^p y^{d-1-p-e} z^e$ is a multiple of a minimal generator of $I$ of the form $x^i y^j z^k$. The orthogonalized coordinates of $E_j$ are $(p + e, p)$. Hence there are 
\[
\begin{pmatrix}
 p + e - s + s - p \\
 s - p
\end{pmatrix} = \begin{pmatrix}
 e \\
 s - p
\end{pmatrix}
\]
lattice paths in $\mathbb{Z}^2$ from $A_i$ to $E_j$. By definition, this is the $(i, j)$-entry of the lattice path matrix $N$.

The monomial label of the end point $E_j$ corresponds to the polynomial
\[
x^p y^{d-1-p-e} (x + y)^e = \sum_{k=0}^{e} \binom{e}{k} x^p + k y^{d-1-p-k}
\]
in $G_2$. Thus, its coefficient of the monomial label $x^s y^{d-1-s}$ is $N(i, j)$. It follows that the matrix $M$ has the form
\[
M = \begin{pmatrix}
 \mathcal{I}_{d-b} & * & 0 \\
 0 & N & 0 \\
 0 & * & \mathcal{I}_{d-a}
\end{pmatrix},
\]
where we used $\mathcal{I}_k$ to denote the $k \times k$ identity matrix.

Notice that the matrices $M$ and $N$ have $d = \dim_K [S]_{d-1}$ and $a + b - d$ rows, respectively. We conclude that
\[
\dim_K [S/J]_{d-1} = d - \dim_K [J]_{d-1} = d - \text{rank } M = a + b - d - \text{rank } N = \dim_K \ker N^T,
\]
as claimed. \hfill \Box

The last result provides another way for checking whether the multiplication by $x + y + z$ has maximal rank.

**Corollary 4.14.** Let $I$ be a monomial ideal in $R = K[x, y, z]$. Then the multiplication map
\[
\varphi_d = \times (x + y + z) : [R/I]_{d-2} \to [R/I]_{d-1}
\]
has maximal rank if and only if $N = N(T_d(I))$ has maximal rank.

**Proof.** Consider the exact sequence
\[
[R/I]_{d-2} \xrightarrow{\varphi_d} [R/I]_{d-1} \to [R/(I, x + y + z)]_{d-1} \to 0.
\]
It gives that $\varphi_d$ has maximal rank if and only if 
\[
\max \{ 0, \dim_K [R/I]_{d-1} - \dim_K [R/I]_{d-2} \} = \dim_K [R/(I, x + y + z)]_{d-1}.
\]
By Proposition 4.13, this is equivalent to
\[
\dim_K \ker N^T = \max \{ 0, \dim_K [R/I]_{d-1} - \dim_K [R/I]_{d-2} \}.
\]
Recall that, by construction, the vertices of the lattice \( L(T_d(I)) \) are on edges of the triangles that are parallel to the upper-left edge of \( T_d \), where this edge belongs to just an upward-pointing triangle (\( A \)-vertices), just a downward-pointing triangle (\( E \)-vertices), or an upward- and a downward-pointing unit triangle (all other vertices). Suppose there are \( m \) \( A \)-vertices, \( n \) \( E \)-vertices, and \( t \) other vertices. Then there are \( m + t \) upward-pointing triangles and \( n + t \) downward-pointing triangles, that is, \( \dim_K [R/I]_{d-1} = m + t \) and \( \dim_K [R/I]_{d-2} = n + t \). Hence
\[
\dim_K [R/I]_{d-1} - \dim_K [R/I]_{d-2} = (m + t) - (n + t) = m - n.
\]
Since the rows and columns of \( N \) are indexed by \( A \)- and \( E \)-vertices, respectively, \( N \) is an \( m \times n \) matrix. Hence, \( N \) has maximal rank if and only if
\[
\dim_K \ker N^T = \max\{0, m - n\} = \max\{0, \dim_K [R/I]_{d-1} - \dim_K [R/I]_{d-2}\}.
\]

Now, using Corollary 4.14 instead of Corollary 4.6, we obtain a result that is analogous to Corollary 4.8.

**Corollary 4.15.** Let \( I \) be an Artinian monomial ideal in \( R = K[x, y, z] \), where \( K \) is infinite, and suppose the degrees of the socle generators of \( R/I \) are at least \( d - 2 \). Then:

(i) If \( 0 \neq h_{R/I}(d - 1) = h_{R/I}(d) \), then \( R/I \) has the weak Lefschetz property if and only if \( \det N(T_d(I)) \) is not zero in \( K \).

(ii) If \( h_{R/I}(d - 2) < h_{R/I}(d - 1) \) and \( h_{R/I}(d - 1) > h_{R/I}(d) \), then \( R/I \) has the weak Lefschetz property if and only if \( N(T_d(I)) \) and \( N(T_{d+1}(I)) \) both have a maximal minor that is not zero in \( K \).

In the case where \( T = T_d(I) \) is balanced we interpreted the determinant of \( N(T) \) as the enumeration of signed families of non-intersecting lattice paths in the lattice \( L(T) \) (see Theorem 4.12). In general, we can similarly interpret the maximal minors of \( N(T) \) by removing \( A \)-vertices or \( E \)-vertices from \( L(T) \), since the rows and columns of \( N(T) \) are indexed by these vertices. Note that removing the \( A \)- and \( E \)-vertices is the same as removing the associated unit triangles in \( T \). For example, \( U' \) in Figure 4.2(i) corresponds to removing the starting point \( A_1 \) from \( U \). It follows that the maximal minors of \( N(T) \) are exactly the determinants of maximal minors of \( T \) (see Remark 4.9) that are obtained from \( T \) by removing only unit triangles corresponding to \( A \)- and \( E \)-vertices. We call such a maximal minor a *restricted maximal minor* of \( T \).

Clearly, \( N(T) \) has maximal rank if and only if there is a restricted maximal minor \( U \) of \( T \) such that \( N(U) \) has maximal rank. As a consequence, for a \( \Delta \)-heavy region \( T \), it is enough to check the restricted maximal minors in order to determine whether \( Z(T) \) has maximal rank.

**Proposition 4.16.** Let \( T = T_d(I) \) be an \( \Delta \)-heavy triangular region. Then \( Z(T) \) has maximal rank if and only if there is a restricted maximal minor \( U \) of \( T \) such that \( Z(U) \) has maximal rank.

**Proof.** By Corollaries 4.6 and 4.14 we have that \( Z(T) \) has maximal rank if and only if \( N(T) \) has maximal rank. Since each restricted maximal minor \( U \) of \( T \) is obtained by removing upward-pointing triangles, it is the triangular region of some monomial ideal. Thus, Theorem 4.12 gives \( |\det Z(U)| = |\det N(U)| \). \( \square \)
Remark 4.17. The preceding proposition allows us to reduce the number of minors of $Z(T)$ that need to be considered. In Example 4.10(i), there are 11 maximal minors of $T_5(I)$, but only 2 restricted maximal minors.

In the special case of a hexagonal region as in Proposition 5.3 below, Proposition 4.16 was observed by Li and Zanello in [23, Theorem 3.2].

We continue to consider Example 4.10, using lattice path matrices now.

**Example 4.18.** Recall the ideal $I = (x^4, y^4, z^4, x^2z^2)$ from Example 4.10. By Corollary 4.15, $R/I$ has the weak Lefschetz property if and only if $N(T_5(I))$ and $N(T_6(I))$ have maximal rank. Since $N(T_5(I))$ is a $2 \times 1$ matrix, we need to remove 1 $A$-vertex to get a maximal minor (see $U'$ in Figure 4.2(i) for one of the two choices). Both choices have signed enumeration 4. Since $N(T_6(I))$ is a $0 \times 2$ matrix we need to remove 2 $E$-vertices to get a restricted maximal minor. The region $U''$ in Figure 4.2(ii) is the only choice, and the signed enumeration is 1. Thus, we see again that $R/I$ has the weak Lefschetz property if and only if the characteristic of the base field $K$ is not 2.

5. Explicit enumerations

Before applying the methods developed in the previous sections to studying the weak Lefschetz property, we consider the problem of determining enumerations. We begin by discussing some general techniques. We then use these to evaluate some determinants.

5.1. Replacements.

Recall that, by Lemma 3.1, removing a tileable region does not affect unsigned tileability. Using the structure of the bi-adjacency matrix $Z(T)$, we analyze how removing a balanced region affects signed enumerations.

**Proposition 5.1.** Let $T \subset T_d$ be a balanced subregion, and let $U$ be a balanced monomial subregion of $T$. Then $|\det Z(T)| = |\det Z(T \setminus U) \cdot \det Z(U)|$.

**Proof.** Recall that the rows of the matrices $Z(\cdot)$ are indexed by the downward-pointing triangles, and the columns of the matrices $Z(\cdot)$ are indexed by the upward-pointing triangles, using the reverse-lexicographic order of their monomial labels. Reorder the downward-pointing (respectively, upward-pointing) triangles of $T$ so that the triangles of $T \setminus U$ come first and the triangles of $U$ come second, where we preserve the internal order of the triangles of $T \setminus U$ and $U$. Using this new ordering, we reorder the rows and columns of $Z(T)$. The result is a block matrix

$$
\begin{pmatrix}
Z(T \setminus U) & X \\
Y & Z(U)
\end{pmatrix}.
$$

Since the downward-pointing triangles of $U$ are not adjacent to any upward-pointing triangle of $T \setminus U$, the matrix $Y$ is a zero matrix. Thus, the claims follow by using the block matrix formula for determinants.

In particular, if we remove a monomial region with a unique lozenge tiling, then we do not modify the enumerations of lozenge tilings in that region. This is true in greater generality.

**Proposition 5.2.** Let $T \subset T_d$ be a balanced subregion, and let $U$ be any subregion of $T$ such that each lozenge tiling of $T$ induces a tiling of $U$ and all the induced tilings of $U$ agree. Then we have:
(i) $Z(T)$ has maximal rank if and only if $Z(T \setminus U)$ has maximal rank.

(ii) $|\det Z(T)| = |\det Z(T \setminus U)|$.

Proof. Part (ii) follows from Theorem 4.3, and it implies part (i). \qed

We point out the following special case.

**Corollary 5.3.** Let $T = T_d(I)$ be a balanced triangular region with two punctures $P_1$ and $P_2$ that overlap or touch each other. Let $P$ be the minimal covering region of $P_1$ and $P_2$. Then the following statements hold.

(i) $\text{perm } Z(T) = \text{perm } Z(T \setminus P)$; and

(ii) $|\det Z(T)| = |\det Z(T \setminus P)|$.

Proof. The monomial region $U := P \setminus (P_1 \cup P_2)$ is uniquely tileable. Hence the claims follows from Proposition 5.2 because $T \setminus U = T \setminus P$. \qed

We give an example of such a replacement.

**Example 5.4.** Let $T = T_d(I)$ be a balanced triangular region. Suppose the ideal $I$ has minimal generators $x^{a+b} y^b z^c$ and $x^a y^{b+\beta} z^{c+\gamma}$. The punctures associated to these generators overlap or touch if and only if $a + \alpha + b + \beta + c + \gamma \leq d$. In this case, the minimal overlapping region $U$ of the two punctures is associated to the greatest common divisor $x^a y^b z^c$. Assume that $U$ is not overlapped by any other puncture of $T$. Then $U$ is uniquely tileable. Hence the regions $T$ and $T' = T \setminus U = T_d(I, x^a y^b z^c)$ have the same enumerations. Note that the ideal $(I, x^a y^b z^c)$ has fewer minimal generators than $I$.

The above procedure allows us in some cases to pass from a triangular region to a triangular region with fewer punctures. Enumerations are typically more amenable to explicit evaluations if we have few punctures, as we will see in the next subsection.

5.2. **Determinants.**

MacMahon [24] computed the number of plane partitions (finite two-dimensional arrays that weakly decrease in all columns and rows) in an $a \times b \times c$ box as (see, e.g., [33, Page 261])

$$\text{Mac}(a, b, c) := \frac{\mathcal{H}(a) \mathcal{H}(b) \mathcal{H}(c) \mathcal{H}(a+b+c)}{\mathcal{H}(a+b) \mathcal{H}(a+c) \mathcal{H}(b+c)},$$

where $a$, $b$, and $c$ are nonnegative integers and $\mathcal{H}(n) := \prod_{i=0}^{n-1} i!$ is the hyperfactorial of $n$. David and Tomei proved in [14] that plane partitions in an $a \times b \times c$ box are in bijection with lozenge tilings in a hexagon with side lengths $(a, b, c)$, that is, a hexagon whose opposite sides are parallel and have lengths $a, b, \text{ and } c$, respectively. However, Propp states on [33, Page 258] that Klarner was likely the first to have observed this. See Figure 5.1 for an illustration of the connection.

We use the above formula in several explicit determinantal evaluations. As we are also interested in the prime divisors of the various non-trivial enumerations we consider, we note that $\text{Mac}(a, b, c) > 0$ and the prime divisors of $\text{Mac}(a, b, c)$ are at most $a + b + c - 1$ if $a, b, \text{ and } c$ are positive. This bound is sharp if $a + b + c - 1$ is a prime number. If one of $a, b, \text{ or } c$ is zero, then $\text{Mac}(a, b, c) = 1$.

As a first example, we enumerate the (signed) lozenge tilings of a hexagon.
Figure 5.1. An example of a 2 × 6 × 3 plane partition and the associated lozenge tiling of a hexagon. The grey lozenges are the tops of the boxes.

Proposition 5.5. Let \( a, b, \) and \( c \) be positive integers such that \( a \leq b + c, \ b \leq a + c, \) and \( c \leq a + b. \) Suppose that \( d = \frac{1}{2}(a+b+c) \) is an integer. Then \( T = T_d(x^a, y^b, z^c) \) is a hexagon with side lengths \( (d - a, d - b, d - c) \) and

\[
|\det Z(T)| = \text{perm } Z(T) = Mac(d - a, d - b, d - c).
\]

Moreover, the prime divisors of the enumeration are bounded above by \( d - 1. \)

Proof. As \( a \leq b + c, \) we have \( d = \frac{1}{2}(a + b + c) \geq \frac{1}{2}(a + a) = a. \) Similarly, \( d \geq b \) and \( d \geq c. \) Thus \( T \) has three punctures of side length \( d - a, d - b, \) and \( d - c \) in the three corners. Moreover, \( d - (d - a + d - b) = d - c \) is the distance between the punctures of length \( d - a \) and \( d - b, \) and similarly for the other two puncture pairings. Thus, the unit triangles of \( T \) form a hexagon with side lengths \( (d - a, d - b, d - c). \) By MacMahon’s formula we have \( \text{perm } Z(T) = Mac(d - a, d - b, d - c). \) Since \( T \) is simply-connected, Proposition 4.4 gives \( |\det Z(T)| = \text{perm } Z(T) = Mac(d - a, d - b, d - c). \) The prime divisors of this integer are bounded above by \( (d - a) + (d - b) + (d - c) - 1 = d - 1. \) □

Combining Propositions 5.1 and 5.5 we get the enumeration for a slightly more complicated triangular region. (We will use this observation in Section 7.) Clearly, the process of removing a hexagon from a puncture can be repeated.

Corollary 5.6. Let \( T = T_d(x^{a+\alpha}, y^b, z^c, x^\alpha y^\beta, x^\alpha z^\gamma), \) where the quadruples \( (a, b, c, d) \) and \( (\alpha, \beta, \gamma, d - a) \) are both as in Proposition 5.5. In particular, \( a + \alpha + \beta + \gamma = b + c \) and \( d = \frac{1}{2}(a + b + c). \) Then

\[
|\det Z(T)| = \text{perm } Z(T) = Mac(d - a, d - b, d - c) Mac(d - a - \alpha, d - a - \beta, d - a - \gamma),
\]

and the prime divisors of the enumeration are bounded above by \( d - 1. \)

Proof. The region \( T \) is obtained from \( T_d(x^a, y^b, z^c) \) by replacing the puncture associated to \( x^a \) by \( T_{d-a}(x^\alpha, y^\beta, z^\gamma). \) See Figure 5.2. We conclude by using Proposition 5.1. □

Figure 5.2. A hexagon with a puncture replaced by a hexagon.
As preparation for the next enumeration, we need a more general determinant calculation, which may be of independent interest.

**Lemma 5.7.** Let $M$ be an $n$-by-$n$ matrix with entries

$$(M)_{i,j} = \begin{cases} 
\frac{p}{q + j - i} & \text{if } 1 \leq j \leq m, \\
\frac{p}{q + r + j - i} & \text{if } m + 1 \leq j \leq n,
\end{cases}$$

where $p, q, r,$ and $m$ are nonnegative integers and $1 \leq m \leq n$. Then

$$\det M = \text{Mac}(m, q, r) \frac{\mathcal{H}(q + r) \mathcal{H}(p - q) \mathcal{H}(n + r) \mathcal{H}(n + p)}{\mathcal{H}(n + p - q) \mathcal{H}(n + q + r) \mathcal{H}(p) \mathcal{H}(r)}.$$ 

**Proof.** We begin by using [8, Equation (12.5)] to evaluate $\det M$ to be

$$\prod_{1 \leq i < j \leq n} (L_j - L_i) \prod_{i=1}^{n} \frac{(p + i - 1)!}{(n + p - L_i)!(L_i - 1)!},$$

where

$$L_j = \begin{cases} 
q + j & \text{if } 1 \leq j \leq m, \\
q + r + j & \text{if } m + 1 \leq j \leq n.
\end{cases}$$

If we split the products in the previously displayed equation relative to the split in $L_j$, then we obtain the following equations:

$$\prod_{1 \leq i < j \leq n} (L_j - L_i) = \left( \prod_{1 \leq i < j \leq m} (j - i) \right) \left( \prod_{m < i < j \leq n} (j - i) \right) \left( \prod_{1 \leq i < j \leq n} (r + j - i) \right)$$

and

$$\prod_{i=1}^{n} \frac{(p + i - 1)!}{(n + p - L_i)!(L_i - 1)!} = \left( \prod_{i=1}^{n} (p + i - 1)! \right) \left( \prod_{i=1}^{m} \frac{1}{(n + p - q - i)!(q + i - 1)!} \right)$$

$$\left( \prod_{i=m+1}^{n} \frac{1}{(n + p - q - r - i)!(q + r + i - 1)!} \right)$$

$$= \left( \frac{\mathcal{H}(n + p)}{\mathcal{H}(p)} \right) \left( \frac{\mathcal{H}(n + p - m - q) \mathcal{H}(q)}{\mathcal{H}(n + p - q) \mathcal{H}(m + q)} \right)$$

$$\left( \frac{\mathcal{H}(p - q - r) \mathcal{H}(m + q + r)}{\mathcal{H}(n + p - m - q - r) \mathcal{H}(n + q + r)} \right).$$

Bringing these equations together we get that $\det M$ is

$$\frac{\mathcal{H}(m) \mathcal{H}(q) \mathcal{H}(r) \mathcal{H}(m + q + r) \mathcal{H}(n - m) \mathcal{H}(p - q - r) \mathcal{H}(n + p - m - q)}{\mathcal{H}(m + r) \mathcal{H}(m + q) \mathcal{H}(n + r - m) \mathcal{H}(n + p - m - q - r) \mathcal{H}(p) \mathcal{H}(n + p - q) \mathcal{H}(n + q + r)},$$

which, after minor manipulation, yields the claimed result. \qed
Remark 5.8. The preceding lemma generalizes [23, Lemma 2.2], which handles the case $r = 1$. Furthermore, if $r = 0$, then $\det M = \text{Mac}(n, p - q, q)$, as expected (see the running example, $\det \left( \begin{array}{c} a + b \\ a_{i+j} \end{array} \right)$, in [20]).

We now show that a tileable, simply-connected triangular region with four non-floating punctures has a Mahonian-type determinant. This particular region is of interest in Section 7. While in the previous evaluations we considered a bi-adjacency matrix, we work primarily with a lattice path matrix this time and then use Theorem 4.12.

Proposition 5.9. Let $T = T_d(x^a, y^b, z^c, x^\alpha y^\beta)$, where $d = \frac{1}{3}(a + b + c + \alpha + \beta)$ is an integer, $0 < \alpha < a$, $0 < \beta < b$, and $\max\{a, b, c, \alpha + \beta\} \leq d \leq \min\{a + \beta, \alpha + b, a + c, b + c\}$. Then $|\det Z(T)| = \text{perm} Z(T)$ is

$$\text{Mac}(a + \beta - d, d - a, d - (\alpha + \beta)) \frac{\text{Mac}(\alpha + b - d, d - b, d - (\alpha + \beta))}{\text{Mac}(\alpha + b - d, d - b, d - (\alpha + \beta))} \times \frac{\text{Mac}(\alpha + b - d, d - b, d - (\alpha + \beta))}{\text{Mac}(\alpha + b - d, d - b, d - (\alpha + \beta))} \times \frac{\text{Mac}(\alpha + b - d, d - b, d - (\alpha + \beta))}{\text{Mac}(\alpha + b - d, d - b, d - (\alpha + \beta))} \times \frac{\text{Mac}(\alpha + b - d, d - b, d - (\alpha + \beta))}{\text{Mac}(\alpha + b - d, d - b, d - (\alpha + \beta))}.$$

Moreover, the prime divisors of the enumeration are bounded above by $d - 1$.

Proof. Note that $\max\{a, b, c, \alpha + \beta\} \leq d$ implies that all four punctures have nonnegative side length. Furthermore, the condition $d \leq \min\{a + \beta, \alpha + b, a + c, b + c\}$ guarantees that none of the punctures overlap. See Figure 5.3.

We now compute the lattice path matrix $N(T)$ as introduced in Subsection 4.2. Recall that a point in the lattice $L(T)$ with label $x^u y^v z^{d-1-(u+v)}$ is identified with the point $(d-1-v, u) \in \mathbb{Z}^2$. Thus, the starting points of the lattice paths are

$$A_i = \begin{cases} (d - b - i - 1, d - b + i - 1) & \text{if } 1 \leq i \leq \alpha + b - d, \\ (2d - (\alpha + \beta + b) + i - 1, 2d - (\alpha + \beta + b) + i - 1) & \text{if } \alpha + b - d < i \leq d - c. \end{cases}$$

For the end points of the lattice paths, we get

$$E_j = (c - 1 + j, j - 1), \quad \text{where } 1 \leq j \leq d - c.$$

Thus, the entries of the lattice path matrix $N(T)$ are

$$(N(T))_{i,j} = \begin{cases} \left( \begin{array}{c} c \\ d - b + i - j \end{array} \right) & \text{if } 1 \leq i \leq \alpha + b - d, \\ \left( \begin{array}{c} 2d - (\alpha + \beta + b) + i - j \\ c \end{array} \right) & \text{if } \alpha + b - d < i \leq d - c. \end{cases}$$

Transposing $N(T)$, we get a matrix of the form in Lemma 5.7 where $m = \alpha + b - d$, $n = d - c$, $p = c$, $q = d - b$, and $r = d - (\alpha + \beta)$. Thus, we know $\det N(T)$. Since $T$ is simply-connected, Proposition 4.14 and Theorem 4.12 give $\text{perm} Z(T) = |\det Z(T)| = \det N(T)$.

Finally, as $d - \alpha$ and $d - \beta$ are smaller than $d$, the prime divisors of $\det N(T) = |\det Z(T)|$ are bounded above by $d - 1$. \qed

Remark 5.10. The evaluation of the determinant in Proposition 5.9 includes two Mahonian terms and a third non-Mahonian term. The Mahonian terms can be identified in the triangular region. See Figure 5.3 where the darkly-shaded hexagons correspond to the Mahonian terms. It is not clear (to us) where the third term comes from, though it may be of interest that if one subtracts $d - (\alpha + \beta)$ from each hyperfactorial parameter, before the evaluation, then what remains is $\text{Mac}(d - a, d - b, d - c)$. 

Figure 5.3. The darkly-shaded hexagons correspond to the two Mahonian terms.

6. Complete intersections

In this short section we give a first illustration of our methods by applying them to the Artinian monomial ideals of $R = K[x, y, z]$ with the fewest number of generators, that is, to the ideals of the form $I = (a^a, y^b, z^c)$. These are monomial complete intersections and exactly the Artinian monomial ideals of $R$ with type 1. The question whether they have the weak Lefschetz property has motivated a great deal of research (see [29] and Remark 6.3 below).

Throughout the remainder of this paper we assume that the base field is infinite. Recall the following result of Reid, Roberts, and Roitman about the shape of Hilbert functions of complete intersections.

Lemma 6.1. [34, Theorem 1] Let $I = (a^a, y^b, z^c)$, where $a, b, c$ are positive integers. Then the Hilbert function $h = h_{R/I}$ of $R/I$ has the following properties:

(i) $h(j - 2) < h(j - 1)$ if and only if $1 \leq j < \min\{a + b, a + c, b + c, \frac{1}{2}(a + b + c)\}$;
(ii) $h(j - 2) = h(j - 1)$ if and only if $\min\{a + b, a + c, b + c, \frac{1}{2}(a + b + c)\} \leq j \leq \max\{a, b, c, \frac{1}{2}(a + b + c)\}$; and
(iii) $h(j - 2) > h(j - 1)$ if and only if $\max\{a, b, c, \frac{1}{2}(a + b + c)\} < j \leq a + b + c - 1$.

Depending on the characteristic of the base field we get the following sufficient conditions that guarantee the weak Lefschetz property.

Theorem 6.2. Let $I = (x^a, y^b, z^c)$, where $a, b, c$ are positive integers. Set $d = \lceil \frac{a + b + c}{2} \rceil$. Then:

(i) If $d < \max\{a, b, c\}$, then $R/I$ has the weak Lefschetz property, regardless of the characteristic of $K$.
(ii) If $a + b + c$ is even, then $R/I$ has the weak Lefschetz property in characteristic $p$ if and only if $p$ does not divide $\text{Mac}(d - a, d - b, d - c)$.
(iii) If $a + b + c$ is odd, then $R/I$ has the weak Lefschetz property in characteristic $p$ if and only if $p$ does not divide any of the integers

$$\frac{(d-1)}{(a-1)} \left( \frac{d-c}{a-i-1} \right) \text{Mac}(d - a - 1, d - b, d - c),$$

where $d - 1 - b < i < a$.

In any case, $R/I$ has the weak Lefschetz property in characteristic $p$ if $p = 0$ or $p \geq \lceil \frac{a+b+c}{2} \rceil$. 
Proof. The algebra $R/I$ has exactly one socle generator. It has degree $a + b + c - 3 \geq d - 2$.

If $d < \max\{a, b, c\}$, then without loss of generality we may assume $a > d$, that is, $a > b + c$. In this case, $T_d(I)$ has two punctures, one of length $d - b$ and one of length $d - c$. Moreover, $d - b + d - c = a > d$ so the two punctures overlap. Hence $T_d(I)$ is balanced and has a unique tiling. That is, $|\det Z(T_d(I))| = 1$ and so $R/I$ has the weak Lefschetz property, regardless of the characteristic of $K$ (see Corollary 4.8).

Suppose $d \geq \max\{a, b, c\}$. By Lemma 6.1 we have $h_{R/I}(d - 2) \leq h_{R/I}(d - 1) > h_{R/I}(d)$.

Assume $a + b + c$ is even. Then Proposition 5.5 gives that $|\det Z(T_d(I))| = \text{Mac}(d - a, d - b, d - c)$, and so claim (ii) follows by Corollary 4.8.

Assume $a + b + c$ is odd, and so $d = \frac{1}{2}(a + b + c - 1)$. In this case it is enough to find non-trivial maximal minors of $T_d(I)$ and $T_{d+1}(I)$ by Corollary 4.8. Consider the hexagonal regions formed by the present unit triangles of each $T_{d+1}(I)$ and $T_d(I)$. The former hexagon is obtained from the latter by a rotation about $180^\circ$. Thus, we need only consider the maximal minors of $T_d(I)$. This region has exactly one more upward-pointing triangle than downward-pointing triangle. Hence, by Proposition 4.16 it suffices to check whether the restricted maximal minors of $T_d(I)$ have maximal rank. These minors are exactly $T_i := T_d(x^a, y^b, z^c, x^i y^{d-1-i})$, where $d - 1 - b < i < a$. Using Proposition 5.9 we get that $|\det Z(T_i)|$ is

$$\text{Mac}(a - 1 - i, d - a, 1)\text{Mac}(i + b - d, d - b, 1)\frac{\mathcal{H}(d - a + 1)\mathcal{H}(d - b + 1)\mathcal{H}(d - c + 1)\mathcal{H}(d)}{\mathcal{H}(a)\mathcal{H}(b)\mathcal{H}(c)\mathcal{H}(1)},$$

where we notice $d - (i + (d - 1 - i)) = 1$. Since $\text{Mac}(n, k, 1) = \binom{n+k}{k}$ and $\mathcal{H}(n) = (n - 1)!\mathcal{H}(n - 1)$, for positive integers $n$ and $k$, we can rewrite $|\det Z(T_i)|$ as

$$(d - 1 - i)\binom{i}{d - a}\binom{d - b}{d - b}!\binom{d - c}{a - 1}!\frac{(a - 1)!}{(d - b)!} \text{Mac}(d - a - 1, d - b, d - c).$$

Simplifying this expression, we get part (iii).

Finally, using both Propositions 5.5 and 5.9 we see that the prime divisors of $|\det Z(T_i)|$ are bounded above by $d - 1$ in each case. \hfill $\square$

As announced, we briefly comment on the history of the last result and the research it motivated.

Remark 6.3. The presence of the weak Lefschetz property for monomial complete intersections has been studied by many authors. The fact that all monomial complete intersections, in any number of variables, have the strong Lefschetz property in characteristic zero was proven first by Stanley [36] using the Hard Lefschetz Theorem. (See [9], and the references contained therein, for more on the history of this theorem.) However, the weak Lefschetz property can fail in positive characteristic.

The weak Lefschetz property in arbitrary characteristic in the case where one generator has much larger degree than the others (case (i) in the preceding proposition) was first established by Watanabe [38, Corollary 2] for arbitrary complete intersections in three variables, not just monomial ones. Migliore and Miró-Roig [26, Proposition 5.2] generalized this to complete intersections in $n$ variables.

Part (ii) of the above result was first established by the authors [10, Theorem 4.3] (with an extra generator of sufficiently large degree), and independently by Li and Zanello [23, Theorem 3.2]. The latter also proved part (iii) above (use $i = a - k$). However, while both papers mentioned the connection to lozenge tilings of hexagons, it was Chen, Guo, Jin,
and Li [5] who provided the first combinatorial explanation. In particular, the case (ii) was studied in [5, Theorem 1.2]. We also note that [23, Theorem 4.3] can be recovered from Theorem 6.2 if we set \( a = \beta + \gamma, \ b = \alpha + \gamma, \) and \( c = \alpha + \beta. \)

More explicit results have been found in the special case where all generators have the same degree, i.e., \( I_a = (x^a, y^a, z^a). \) Brenner and Kaid used the idea of a syzygy gap to explicitly classify the prime characteristics in which \( I_a \) has the weak Lefschetz property [4, Theorem 2.6]. Kustin, Rahmati, and Vraciu used this result in [21], in which they related the presence of the weak Lefschetz property of \( R/I_a \) to the finiteness of the projective dimension of \( I_a : (x^n + y^n + z^n). \) Moreover, Kustin and Vraciu later gave an alternate explicit classification of the prime characteristics in which \( I_a \) has the weak Lefschetz property [22, Theorem 4.3].

As a final note, Kustin and Vraciu [22] also gave an explicit classification of the prime characteristics in which monomial complete intersections in arbitrarily many variables with all generators of the same degree have the weak Lefschetz property. This was expanded by the first author [9, Theorem 7.2] to an explicit classification of the prime characteristics, in which the algebra has the *strong Lefschetz property*. In this work another combinatorial connection was used to study the presence of the weak Lefschetz property for monomial complete intersections in arbitrarily many variables.

### 7. Type 2 monomial ideals

Boij, Migliore, Miro-Roig, Zanello, and the second author proved in [1, Theorem 6.2] that the Artinian monomial algebras of type two in three variables that are *level* have the weak Lefschetz property in characteristic zero. The proof given there is surprisingly intricate and lengthy. In this section, we establish a more general result using techniques derived in the previous sections.

To begin, we describe the Artinian monomial ideals \( I \) in \( R = K[x, y, z] \) such that \( R/I \) has type two, that is, its socle is of the form \( \text{soc}(R/I) \cong K(-s) \oplus K(-t) \). The algebra \( R/I \) is level if the socle degrees \( s \) and \( t \) are equal. The classification in the level case has been established in [1, Proposition 6.1]. The following more general result is obtained similarly.

**Lemma 7.1.** Let \( I \) be an Artinian monomial ideal in \( R = K[x, y, z] \) such that \( R/I \) is of type 2. Then, up to a change of variables, \( I \) has one of the following two forms:

1. \( I = (x^a, y^b, z^c, x^\alpha y^\beta), \) where \( 0 < \alpha < a \) and \( 0 < \beta < b. \) In this case, the socle degrees of \( R/I \) are \( a + \beta + c - 3 \) and \( \alpha + b + c - 3. \) Thus, \( I \) is level if and only if \( a - \alpha = b - \beta. \)

2. \( I = (x^a, y^b, z^c, x^\alpha y^\beta, x^\alpha z^\gamma), \) where \( 0 < \alpha < a, \ 0 < \beta < b, \) and \( 0 < \gamma < c. \) In this case, the socle degrees of \( R/I \) are \( a + \beta + \gamma - 3 \) and \( \alpha + b + c - 3. \) Thus, \( I \) is level if and only if \( a - \alpha = b - \beta + c - \gamma. \)

**Proof.** We use Macaulay-Matlis duality. An Artinian monomial algebra of type two over \( R \) arises as the inverse system of two monomials, say \( x^{a_1} y^{b_1} z^{c_1} \) and \( x^{a_2} y^{b_2} z^{c_2}, \) such that one does not divide the other. Thus we may assume without loss of generality that \( a_1 > a_2 \) and \( b_1 < b_2. \) We consider two cases: \( c_1 = c_2 \) and \( c_1 \neq c_2. \)

Suppose first that \( c_1 = c_2. \) Then the annihilator of the monomials is the ideal

\[
(x^{a_2+1}, y^{b_2+1}, z^{c_1+1}) \cap (x^{a_1+1}, y^{b_1+1}, z^{c_1+1}) = (x^{a_1+1}, y^{b_2+1}, z^{c_1+1}, x^{a_2+1} y^{b_1+1}),
\]

which is the form in (i). By construction, the socle elements are \( x^{a_1} y^{b_1} z^{c_1} \) and \( x^{a_2} y^{b_2} z^{c_1}. \)
Now suppose $c_1 \neq c_2$; without loss of generality we may assume $c_1 < c_2$. Then the annihilator of the monomials is the ideal
\[(x^{a_1+1}, y^{b_1+1}, z^{c_1+1}) \cap (x^{a_2+1}, y^{b_2+1}, z^{c_2+1}) = (x^{a_1+1}, y^{b_2+1}, z^{c_2+1}, x^{a_2+1}, y^{b_1+1}, x^{a_2+1}z^{c_1+1}),\]
which is the form in (ii). By construction, the socle elements are $x^{a_1}y^{b_1}z^{c_1}$ and $x^{a_2}y^{b_2}z^{c_2}$. □

We now give a complete classification of the type two algebras that have the weak Lefschetz property in characteristic zero.

**Theorem 7.2.** Let $I$ be an Artinian monomial ideal in $R = K[x, y, z]$, where $K$ is a field of characteristic zero, such that $R/I$ is of type 2. Then $R/I$ fails to have the weak Lefschetz property in characteristic zero if and only if $I = (x^a, y^b, z^c, x^ay^b, x^az^c)$, up to a change of variables, where $0 < \alpha < a$, $0 < \beta < b$, and $0 < \gamma < c$, and there exists an integer $d$ with
\[
\max \left\{ a, \alpha + \beta, \alpha + \gamma, \frac{a + \alpha + \beta + \gamma}{2} \right\} < d < \min \left\{ a + \beta + \gamma, \frac{a + b + c}{2}, b + c, \alpha + c, \alpha + b \right\}.
\]

**Proof.** According to Corollary 4.11, for each integer $d > 0$, we have to decide whether the bi-adjacency matrix $Z(T_d(I))$ has maximal rank. This is always true if $d = 1$. Let $d \geq 2$.

By Lemma 4.4, we may assume that $I$ has one of two forms given there. The difference between the two forms is an extra generator, $x^\alpha z^\gamma$. In order to determine the rank of $Z(T_d(I))$ we split $T = T_d(I)$ across the horizontal line $\alpha$ units from the bottom edge. We call the monomial subregion above the line, which is the subregion associated to $x^\alpha$, the *upper portion* of $T$, denoted by $T^u$, and we call the isosceles trapezoid below the line the *lower portion* of $T$, denoted by $T^l$. Note that $T^u$ is empty if $d \leq \alpha$. Both portions, $T^u$ and $T^l$, are hexagons, i.e., triangular regions associated to complete intersections. In particular, if $I$ has four generators, then $T^u = T_{d-\alpha}(x^{a-\alpha}, y^\beta, z^c)$. Similarly, if $I$ has five generators, then $T^u = T_{d-\alpha}(x^{a-\alpha}, y^\beta, z^\gamma)$. In both cases $T^l$ is $T_d(x^\alpha, y^b, z^c)$. See Figure 7.1 for an illustration of this decomposition.

After reordering rows and columns of the bi-adjacency matrix $Z(T)$, it becomes a block matrix of the form
\[
Z = \begin{pmatrix}
Z(T^u) & 0 \\
Y & Z(T^l)
\end{pmatrix}
\]
because the downward-pointing triangles in $T^u$ are not adjacent to any upward-pointing triangles in $T^l$. For determining when $Z$ has maximal rank, we study several cases, depending on whether $T^u$ and $T^l$ are $\triangle$-heavy, balanced, or $\triangledown$-heavy.

First, suppose one of the following conditions is satisfied: (i) $T^u$ or $T^l$ is balanced, (ii) $T^u$ and $T^l$ are both $\triangle$-heavy, or (iii) $T^u$ and $T^l$ are both $\triangledown$-heavy. In other words, $T^u$ and $T^l$ do not “favor” triangles of opposite orientations. Since $T^u$ and $T^l$ are triangular regions associated to complete intersections, both $Z(T^u)$ and $Z(T^l)$ have maximal rank by Theorem 6.2. Combining non-vanishing maximal minors of $Z(T^u)$ and $Z(T^l)$, if follows that the matrix $Z$ has maximal rank as well.

Second, suppose $T^u$ is $\triangle$-heavy and $T^l$ is $\triangledown$-heavy. We will show that $Z$ has maximal rank in this case.

Let $t_u = \# \triangle(T^u) - \# \triangledown(T^u)$ and $t_l = \# \triangledown(T^l) - \# \triangle(T^l)$ be the number of excess triangles of each region. In a first step, we show that we may assume $t_u = t_l$. To this end
we remove enough of the appropriately oriented triangles from the more unbalanced of $T_u$ and $T_l$ until both regions are equally unbalanced. Set $t = \min\{t_u, t_l\}$.

Assume $T_u$ is more unbalanced, i.e., $t_u > t$. Since $T_u$ is $\Delta$-heavy, the top $t_u$ rows of $T_d$ below the puncture associated to $x^a$ do not have a puncture. Thus, we can remove the top $t_u - t$ upward-pointing triangles in $T_u$ along the upper-left edge of $T_d$, starting at the puncture associated to $x^a$, if present, or in the top corner otherwise. Denote the resulting subregion of $T$ by $T'$. Notice that $Z$ has maximal rank if $Z(T')$ has maximal rank. Furthermore, the $t_u - t$ rows in which $T$ and $T'$ differ are uniquely tileable. Denote this subregion of $T'$ by $U$ (see Figure 7.2(i) for an illustration). By construction, the upper and the lower portion $T_u'$ and $T_l' = T'$, respectively, of $T' \setminus U$ are equally unbalanced. Moreover, $Z(T')$ has maximal rank if and only if $Z(T' \setminus U)$ has maximal rank by Proposition 5.2. As desired, $T$ and $T' \setminus U$ have the same shape.

Assume now that $T_l$ is more unbalanced, i.e., $t_l > t$. Since $T_l$ is $\triangledown$-heavy, the two punctures associated to $x^b$ and $x^c$, respectively, cover part of the bottom $t_l$ rows of $T_d$. Thus, we can remove the bottom $t_l - t$ downward-pointing triangles of $T_l$ along the puncture associated to $x^c$. Denote the resulting subregion of $T$ by $T'$. Notice that $Z$ has maximal rank if $Z(T')$ has maximal rank. Again, the $t_l - t$ rows in which $T$ and $T'$ differ form a uniquely tileable subregion. Denote it by $U$. By construction, the upper and the lower portion $T_u'' = T_u$ and $T_l''$, respectively, of $T' \setminus U$ are equally unbalanced. Moreover, $Z(T')$ has maximal rank if and only if $Z(T' \setminus U)$ has maximal rank by Proposition 5.2. As before, $T$ and $T' \setminus U$ have the same shape.

The above discussion shows it is enough to prove that the matrix $Z$ has maximal rank if $t_u = t_l = t$, i.e., $T$ is balanced. Since $T$ has no floating punctures, Proposition 4.4 gives the desired maximal rank of $Z$ once we know that $T$ has a tiling. To see that $T$ is tileable, we first place $t$ lozenges across the line separating $T_u$ from $T_l$, starting with the left-most
such lozenge. Indeed, this is possible since $T^u$ has $t$ more upwards-pointing than downwards-pointing triangles. Next, place all fixed lozenges. The portion of $T^u$ that remains untiled after placing these lozenges is a hexagon. Hence it is tileable. (See Figure 7.2(ii) for an illustration.)

![Diagram of lozenges](image)

(i) A maximal minor of $T$; the removed triangle is darkly shaded.
(ii) Placing a lozenge on the maximal minor to produce a tiling.

**Figure 7.2.** Let $T = T_{10}(x^8, y^8, z^8, x^3y^5, x^3z^6)$. The lightly-shaded lozenges are fixed lozenges.

Consider now the portion of $T^l$ that remains untiled after placing these lozenges. Since $t$ is at most the number of horizontal rows of $T^l$ this portion is, after a $60^\circ$ rotation, a region as described in Proposition 5.9. Thus it is tileable. Figure 7.3 illustrates this procedure with an example.

![Diagram of 60° rotation](image)

**Figure 7.3.** With $T$ as in Figure 7.2 after a $60^\circ$ rotation $T^l$ becomes a previously described region.

It follows that $T$ is tileable. Therefore $Z$ has maximal rank, as desired.

Finally, suppose $T^u$ is $\triangledown$-heavy and $T^l$ is $\triangle$-heavy. Consider any maximal minor of $Z(T)$. It corresponds to a balanced subregion $T'$ of $T$. Then its upper portion $T'^u$ is still $\triangledown$-heavy, and its lower portion $T'^l$ is $\triangle$-heavy. Hence, any covering of $T'^u$ by lozenges must also cover
some upward-pointing triangles of $T'$. The remaining part of $T''$ is even more unbalanced than $T''$. This shows that $T'$ is not unbalanced. Thus, $Z(T') = 0$ by Theorem 4.3. It follows that $Z$ does not have maximal rank in this case.

The above case analysis proves that $R/I$ fails the weak Lefschetz property if and only if there is an integer $d$ so that the associated regions $T^u$ and $T^l$ are $\nabla$-heavy and $\triangle$-heavy, respectively. It remains to determine when this happens.

If $I$ has only four generators, then no row of $T^u$ has more downward-pointing than upward-pointing triangles. Hence, $T^u$ is not $\nabla$-heavy. It follows that $I$ must have five generators if $R/I$ fails to have the weak Lefschetz property. For such an ideal $I$, the region $T^u = T_{d-\alpha}(x^{\alpha-\gamma}, y^\gamma, z^\gamma)$ is $\nabla$-heavy if and only if

$$\dim_K[R/(x^{\alpha-\gamma}, y^\gamma, z^\gamma)]_{d-\alpha-2} > \dim_K[R/(x^{\alpha-\gamma}, y^\gamma, z^\gamma)]_{d-\alpha-1},$$

and $T^l = T_d(x^\alpha, y^b, z^c)$ is $\triangle$-heavy if and only if

$$\dim_K[R/(x^\alpha, y^b, z^c)]_{d-2} < \dim_K[R/(x^\alpha, y^b, z^c)]_{d-1}.$$

Using Lemma 6.1, a straightforward computation shows that these two inequalities are both true if and only if $d$ satisfies Condition (7.1).

**Remark 7.3.** The above argument establishes the following more precise version of Theorem 7.2.

Let $R/I$ be a Artinian monomial algebra of type 2, where $K$ is a field of characteristic zero, and let $\ell \in R$ be a general linear form. Then the multiplication map $\times \ell : [R/I]_{d-2} \to [R/I]_{d-1}$ does not have maximal rank if and only if $I = (x^3, y^4, z^5, x^3y^2, x^3z^2)$, if $d = 5$ or $d = 6$. Note that $R/J$ has a non-unimodal Hilbert function, $(1, 3, 6, 7, 7, 6, 5, 4, 3, 2, 1)$. Moreover, $J'$ has a non-strict Hilbert function $(1, 3, 3, 3, 3, 2, 1)$.

Using Theorem 7.2, we easily recover [1] Theorem 6.2, one of the main results in the recent memoir [1].

**Example 7.4.** We provide three examples, the latter two come from [1] Example 6.10, with various shapes of Hilbert functions.

(i) Let $I = (x^4, y^4, z^4, x^3y, x^3z)$. Then $d = 5$ satisfies Condition (7.1). Moreover, $T_d(I)$ is a balanced region, and $R/I$ has a strictly unimodal Hilbert function, $(1, 3, 6, 10, 10, 9, 6, 3, 1)$.

(ii) Let $J = (x^3, y^7, z^7, xy^2, xz^2)$. Then Condition (7.1) is satisfied if and only if $d = 5$ or $d = 6$. Note that $R/J$ has a non-unimodal Hilbert function, $(1, 3, 6, 7, 7, 6, 5, 4, 3, 2, 1)$.

(iii) Let $J' = (x^2, y^4, z^4, xy, xz)$. Then $d = 3$ satisfies Condition (7.1). Moreover, $J'$ has a non-strict Hilbert function $(1, 3, 3, 4, 3, 2, 1)$.

Using Theorem 7.2, we easily recover [1] Theorem 6.2, one of the main results in the recent memoir [1].

**Corollary 7.5.** Let $R/I$ be a Artinian monomial algebra of type 2 over a field of characteristic zero. Then $R/I$ has the weak Lefschetz property.

**Proof.** By Theorem 7.2 we know that if $I$ has four generators, then $R/I$ has the weak Lefschetz property. If $I$ has five generators, then it suffices to show that Condition (7.1) is vacuous in this case. Indeed, since $R/I$ is level, we have that $a - \alpha = b - \beta + c - \gamma$ by Lemma 7.4. This implies

$$\frac{a + \alpha + \beta + \gamma}{2} = \frac{2a + b + c}{2} \geq \alpha + \min\{b, c\}.$$
Hence, no integer \( d \) satisfies Condition (7.1). \( \square \)

Moreover, in most of the cases when the weak Lefschetz property holds in characteristic zero, we can give a linear lower bound on the characteristics for which the weak Lefschetz property must hold.

**Corollary 7.6.** Let \( R/I \) be a Artinian monomial algebra of type 2. Suppose that \( R/I \) has the weak Lefschetz property in characteristic zero and that there is no integer \( d \) such that

\[
\alpha, b, c, \frac{a + \beta + \gamma + c}{2}, \frac{a + \alpha + \beta + c}{2} < d < \min\{a + \beta, a + c, a + \alpha + \beta + c\}. 
\]

Then \( R/I \) has the weak Lefschetz property, provided \( K \) has characteristic \( p \geq \left\lfloor \frac{a + b + c}{2} \right\rfloor \).

**Proof.** We use the notation introduced in the proof of Theorem 7.2. Fix any integer \( d \geq 2 \). Recall that, possibly after reordering rows and columns, the bi-adjacency matrix of \( T = T_d(I) \) has the form (see Equation (7.2))

\[
Z = \begin{pmatrix} Z(T^u) & 0 \\ Y & Z(T^l) \end{pmatrix}. 
\]

By assumption, \( d \) does not satisfy Condition (7.1) nor (7.3). This implies that \( T \) has one of the following properties: (i) \( T^u \) or \( T^l \) is balanced, (ii) \( T^u \) and \( T^l \) are both \( \triangle \)-heavy, or (iii) \( T^u \) and \( T^l \) are both \( \triangledown \)-heavy.

The matrices \( Z(T^u) \) and \( Z(T^l) \) have maximal rank by Theorem 6.2 if the characteristic of \( K \) is at least \( \left\lfloor \frac{a - \alpha + \beta + c}{2} \right\rfloor \) and \( \left\lfloor \frac{a + b + c}{2} \right\rfloor \), respectively. Combining non-vanishing maximal minors of \( Z(T^u) \) and \( Z(T^l) \), it follows that the matrix \( Z \) has maximal rank as well if \( \text{char} K \geq \left\lfloor \frac{a + b + c}{2} \right\rfloor \). \( \square \)

In order to fully extend Theorem 7.2 to sufficiently large positive characteristics, it remains to consider the case where \( T^u \) is \( \triangle \)-heavy and \( T^l \) is \( \triangledown \)-heavy. This is more delicate.

**Example 7.7.** Let \( T = T_{10}(x^8, y^8, z^8, x^3y^5, x^3z^6) \) as in Figure 7.2 and let \( T' \) be the maximal minor given in Figure 7.2(i). In each lozenge tiling of \( T' \), there is exactly one lozenge that crosses the splitting line. There are four possible locations for this lozenge; one of these is illustrated in Figure 7.2(ii). The enumeration of lozenge tilings of \( T' \) is thus the sum of the lozenge tilings with the lozenge in each of the four places along the splitting line. Each of the summands is the product of the enumerations of the resulting upper and lower regions. In particular, we have that

\[
|\det N(T')| = 20 \cdot 60 + 45 \cdot 64 + 60 \cdot 60 + 50 \cdot 48 \\
= 2^4 \cdot 3 \cdot 5^2 + 2^6 \cdot 3^2 \cdot 5 + 2^4 \cdot 3^2 \cdot 5^2 + 2^5 \cdot 3 \cdot 5^2 \\
= 2^5 \cdot 3^2 \cdot 5 \cdot 7 \\
= 10080.
\]

Notice that while the four summands only have prime factors of 2, 3, and 5, the final enumeration also has a prime factor of 7.

Still, we can give a bound in this case, though we expect that it is very conservative. It provides the following extension of Theorem 7.2.
Proposition 7.8. Let $R/I$ be a Artinian monomial algebra of type 2 such that $R/I$ has the weak Lefschetz property in characteristic zero. Then $R/I$ has the weak Lefschetz property in positive characteristic, provided $\text{char } K \geq 3^e$, where $e = \frac{1}{2}(\frac{(a+b+c)+2}{2})$.

This follows from Lemma 7.1 and the following general result, which provides an effective bound for Corollary 2.6 in the case of three variables.

Proposition 7.9. Let $R/I$ be any Artinian monomial algebra such that $R/I$ has the weak Lefschetz property in characteristic zero. If $I$ contains the powers $x^a, y^b, z^c$, then $R/I$ has the weak Lefschetz property in positive characteristic whenever $\text{char } K > 3^{\frac{1}{2}(\frac{(a+b+c)+2}{2})}$.

Proof. Define $I' = (x^a, y^b, z^c)$, and let $d'$ be the smallest integer such that $0 \neq h_{R/I'}(d' - 1) \geq h_{R/I'(d')}. Thus, $d' - 1 \leq \frac{1}{2}(a + b + c)$ by Lemma 6.1.

Let $d$ be the smallest integer such that $0 \neq h_{R/I}(d - 1) \geq h_{R/I}(d)$. Then $d \leq d'$, as $I' \subset I$ and adding or enlarging punctures only exacerbates the difference in the number of upward- and downward-pointing triangles. Since $R/I$ has the weak Lefschetz property in characteristic zero, the Hilbert function of $R/I$ is strictly increasing up to degree $d - 1$. Hence, Proposition 2.3 implies that the degrees of non-trivial socle elements of $R/I$ are at least $d - 1$. The socle of $R/I$ is independent of the characteristic of $K$. Therefore Proposition 2.3 shows that, in any characteristic, $R/I$ has the weak Lefschetz property if and only if the bi-adjacency matrices of $T_d(I)$ and $T_{d+1}(I)$ have maximal rank. Each row and column of a bi-adjacency matrix has at most three entries that equal one. All other entries are zero. Moreover the maximal square sub-matrices of $Z(T_d(I))$ and $Z(T_{d+1}(I))$ have at most $h_{R/I}(d-1)$ rows. Since $h_{R/I}(d-1) < h_{R}(d-1) = \binom{d+1}{2} \leq 3e$, Hadamard’s inequality shows that the absolute values of the maximal minors of $Z(T_d(I))$ and $Z(T_{d+1}(I))$, considered as integers, are less than $3^{2e}$. Hence, any prime number $p \geq 3^e$ does not divide any of these non-trivial maximal minors.

As indicated above, we believe that the bound in Proposition 7.8 is far from being optimal. Through a great deal of computer experimentation, we offer the following conjecture.

Conjecture 7.10. Let $I$ be an Artinian monomial ideal in $R = K[x, y, z]$ such that $R/I$ is of type two. If $R/I$ has the weak Lefschetz property in characteristic zero, then $R/I$ also has the weak Lefschetz property in characteristics $p > \frac{1}{2}(a + b + c)$.
