ABSTRACT Microorganisms growing near the boiling point have enormous biotechnological potential but only recently have molecular engineering tools become available for them. We have engineered the hyperthermophilic archaeon Pyrococcus furiosus, which grows optimally at 100°C, to switch its end products of fermentation in a temperature-controlled fashion without the need for chemical inducers. The recombinant strain (LAC) expresses a gene (ldh) encoding lactate dehydrogenase from the moderately thermophilic Caldicellulosiruptor bescii (optimal growth temperature \( T_{\text{opt}} \) of 78°C) controlled by a “cold shock” promoter that is upregulated when cells are transferred from 98°C to 72°C. At 98°C, the LAC strain fermented sugar to produce acetate and hydrogen as end products, and lactate was not detected. When the LAC strain was grown at 72°C, up to 3 mM lactate was produced instead. Expression of a gene from a moderately thermophilic bacterium in a hyperthermophilic archaeon at temperatures at which the hyperthermophile has low metabolic activity provides a new perspective to engineering microorganisms for bioproduct and biofuel formation.

IMPORTANCE Extremely thermostable enzymes from microorganisms that grow near or above the boiling point of water are already used in biotechnology. However, the use of hyperthermophilic microorganisms themselves for biotechnological applications has been limited by the lack of their genetic accessibility. Recently, a genetic system for Pyrococcus furiosus, which grows optimally near 100°C, was developed in our laboratory. In this study, we present the first heterologous protein expression system for a microorganism that grows optimally at 100°C, a first step towards the potential expression of genes involved in biomass degradation or biofuel production in hyperthermophiles. Moreover, we developed the first system for specific gene induction in P. furiosus. As the cold shock promoter for protein expression used in this study is activated at suboptimal growth temperatures of P. furiosus, it is a powerful genetic tool for protein expression with minimal interference of the host’s metabolism and without the need for chemical inducers.

S
since the discovery of hyperthermophiles in the 1980s (1), hyperthermophiles have attracted a great deal of attention due to their ability to grow optimally at temperatures above 80°C. Virtually all are classified within the archaeal domain rather than the bacterial domain. In addition to their evolutionary implications, hyperthermostable enzymes are of high biotechnological interest (2–4), since many industrial processes are facilitated by elevated temperatures and organisms that grow under such conditions can be used without risk of contamination (3). Although the ability to metabolically engineer microorganisms is a prerequisite for their use as whole-cell biocatalysts, the genetic manipulation of hyperthermophiles is a very recent development. Targeted modifications of the chromosome have so far been reported only for those microorganisms growing optimally near 80°C or so, which include Sulfolobus acidocaldarius (optimal growth temperature \( T_{\text{opt}} \) of 80°C) and the related species Sulfolobus solfataricus \( (T_{\text{opt}} \) of 75°C) (5, 6) and Thermococcus kodakarensis \( (T_{\text{opt}} \) of 85°C) (7). Very recently, however, we developed a genetic system for Pyrococcus furiosus, the first for an organism that grows optimally near 100°C (8). P. furiosus is one of the best-studied hyperthermophiles, belonging to the same family as T. kodakarensis but with a much higher optimal growth temperature (9). P. furiosus is a strict anaerobe and obtains carbon and energy for growth by the fermentation of carbohydrates and peptides with organic acids, CO₂, and H₂, as end products (10).

A variant of wild-type P. furiosus (DSM 3638) was recently isolated. This strain takes up DNA very efficiently to create a genetically modified P. furiosus strain (COM1) by the targeted and markerless deletion of the pyrF gene that encodes orotidine-5’-monophosphate (OMP) decarboxylase, which is essential for uracil biosynthesis (8). Moreover, linear DNA could be used to transform P. furiosus, and the DNA was integrated into the chromosome by homologous recombination. The COM1 strain was also used to overexpress a minimal form of the cytoplasmic hydrogenase (SHI) of P. furiosus (11). This study utilized a new selective marker for P. furiosus based on previous work with

*T. kodakarenensis* (12) in which the deletion of the gene (*pdaD*) encoding pyruvoly-dependent arginine decarboxylase led to an auxotrophy for agmatine, an essential intermediate in polyamine biosynthesis (13) and in translation (14). Agmatine is not present in complex growth substrates, such as yeast extract and casein, thus allowing the use of rich media for *P. furiosus* mutant selection.

The availability of a genetic system for an organism growing optimally at 100°C opens up the possibility of engineering the temperature-dependent heterologous expression of genes encoding enzymes that are active at suboptimal growth temperatures for the host. Depending on the temperature, the host organism can have lower metabolic activity or be virtually inactive. For example, the generation time of *P. furiosus* increases from less than 1 h at 98°C to about 7 h at 72°C (15), with little growth below 65°C (9). Production of enzymes optimally active near 70°C or so could give *P. furiosus* new metabolic capabilities at this temperature that it does not have at the optimum near 100°C where the heterologously produced enzymes would likely be inactive. Similarly, at even lower temperatures (≤60°C), *P. furiosus* could be a nonmetabolizing host, and chemical conversions could be accomplished only by the heterologously produced enzymes. While heterologous gene expression has already been reported using the related hyperthermophile, *T. kodakarenensis* (16, 17), this involved genes from archaeal species that grow at temperatures comparable to that of *T. kodakarenensis*. In this study, our goal was to heterologously express in *P. furiosus* a gene from a bacterium that grows at significantly lower temperature and demonstrate temperature-dependent generation of a new end product in the absence of any chemical inducer for gene expression.

The use of temperature to change metabolism might be feasible if, at the higher temperature, the heterologously produced enzymes are unstable and degraded by the hyperthermophile. However, it would obviously be more efficient if the genes that encode the foreign proteins were transcribed only at suboptimal temperatures. In a previous study, we showed that when *P. furiosus* was grown at 72°C, rather than near the optimum at 98°C, or if cells growing at 98°C were “cold shocked” by transferring them to 72°C, the expression of numerous genes was upregulated significantly (15). One of the most highly expressed genes encoded a membrane-bound glycoprotein, the so-called cold-induced protein A, or CipA (PF0190), which was upregulated 26-fold (as determined by quantitative PCR [qPCR] analysis) at 72°C (15). The *cipA* promoter, *PcipA*, was therefore chosen for the attempt to induce expression of a bacterial gene at suboptimal growth temperature for the host.

For proof of principle of a temperature-dependent metabolic switch in *P. furiosus*, we selected a bacterial gene that has no homolog in the *P. furiosus* genome and one that is involved in the metabolism of a compound that *P. furiosus* is not known to produce. The anaerobic bacterium *Caldicellulosiruptor bescii* grows optimally at 78°C by sugar fermentation and produces lactate at millimolar concentrations as the main end product (18). Lactate is generated by the reduction of pyruvate catalyzed by an NADH-dependent lactate dehydrogenase (LDH) encoded by *Cbes_1918* (*ldh*). In contrast, while *P. furiosus* also ferments sugars to pyruvate, its genome does not contain a gene encoding an LDH homolog, and the organism oxidizes pyruvate by pyruvate ferredoxin oxidoreductase to produce acetate, CO₂, and H₂ as the primary products (Fig. 1A). The goal was therefore to express the LDH gene of *C. bescii* in *P. furiosus* under control of the *PcipA* promoter and determine whether any lactate is produced during growth at 72°C, but not at 98°C (Fig. 1A).

**RESULTS**

To construct a *P. furiosus* strain containing the *C. bescii* *ldh* gene under control of the *PcipA* promoter, the *PcipACbes-ldh* gene fusion was cloned in the plasmid vector pSPF300 in *Escherichia coli* (Fig. 2 and Table 1). The agmatine-requiring *P. furiosus* mutant strain, ΔpdaD strain, was used as the host (11). This strain is deficient in agmatine biosynthesis, as the *pdaA* gene is replaced by *pyrF*, an essential gene for uracil biosynthesis (Table 1). The linearized plasmid containing *PcipACbes-ldh* (Fig. 2) was used to complement the *pdaD* gene into the *P. furiosus* chromosome by replacing the *pyrF* gene by homologous recombination. The resulting transformants (Δ*pyrF*) required uracil but did not require agmatine for growth (Fig. 3). Plasmid integration was confirmed by PCR and for one colony by DNA sequencing. The recombinant *P. furiosus* strain was named LAC (Table 1). To investigate the expression of *C. bescii* *ldh* in *P. furiosus* and the production of lactate, the LAC strain was grown in batch culture under three different conditions: (i) in closed, static cultures (400-ml scale) at 72°C and at 98°C with no pH control; (ii) in Ar-sparged, stirred cultures (15-liter scale) at 72°C with pH control; and (iii) in Ar-sparged, stirred cultures at 94°C with a pH control (15-liter scale) followed by rapid cooling of the culture to 72°C within 10 min (cold shock).

The recombinant strains of *P. furiosus* were grown at 98°C and at 72°C in closed, static cultures without a pH control. The Δ*pdaD* and LAC strains grew at 98°C to comparable cell densities after 12 h (>10⁶ cells/ml, >50 μg protein/ml), but at 72°C growth was still very poor even after 45 h (<10⁸ cells/ml, <20 μg protein/ml). Interestingly, cells changed their morphology at 72°C, becoming light refracting, and larger (up to 5 μm), in accordance with the upregulation of the expression of a wide range of genes, including those encoding numerous membrane-bound proteins (15). To determine whether recombinant protein production was successful, the cells were lysed by sonication, and the activity of NAD-dependent lactate dehydrogenase (LDH) was determined in cell-free extracts at 75°C. The activity of NAD-dependent glutamate dehydrogenase (GDH), a well-characterized cytoplasmic enzyme of *P. furiosus* (19), was used as a control. The wild-type, Δ*pdaD*, and LAC strains had comparable specific activities of GDH when...
grown at 72°C (0.09 to 0.11 U mg\(^{-1}\)) and when grown at 98°C (0.14 to 0.27 U mg\(^{-1}\)). LDH activity was not detected (0.05 U mg\(^{-1}\)) in cell-free extracts of any strain grown at 98°C or in extracts of cells of the wild-type and parent strains grown at 72°C. However, extracts of the LAC strain grown at 72°C had high LDH activity (1.8 U mg\(^{-1}\)).

*C. bescii* *ldh* is the first bacterial gene to be expressed and to yield an active enzyme in *P. furiosus* (Fig. 1A). Remarkably, the specific activity of LDH in *P. furiosus* was comparable to that measured in cell-free extracts of *C. bescii* (2.5 U mg\(^{-1}\); Fig. 1B), conditions under which *C. bescii* produces lactate as the major metabolic product. Moreover, while lactate was not detected (<20 mM) in the growth medium of any of the *P. furiosus* strains grown at 98°C or in the wild-type and parent strains grown at 72°C, the medium of the LAC strain contained 0.47 ± 0.14 mM lactate (Fig. 1C).

Growth of the *P. furiosus* LAC strain at 72°C was scaled up in a stirred, pH-controlled fermentor (15 liters), conditions under which good growth of *P. furiosus* is obtained even at this low temperature (15). The organism reached a maximum cell density after approximately 50 h (1 × 10^8 ml\(^{-1}\), 60 µg ml\(^{-1}\)) (Fig. 4A) and remained stable in stationary phase for a further 28 h. The specific activity of LDH in the cell extract was the same as that measured in small-scale cultures and remained unchanged (2.0 ± 0.4 U mg\(^{-1}\)) in exponential (at 38 h [Fig. 4A]), early stationary (at 59 h), and late stationary (at 78 h) growth phase. Consequently, the amount of lactate produced paralleled the cell density. This reached a concentration near 3 mM in stationary phase, which was approximately half of the concentration of acetate that was pro-

**FIG 2** Plasmid vector pMPF301 containing the *pdaD* _P. aeruginosa_Cbes-ldh cassette, 1-kb upstream and downstream flanking regions of the *pdaD* gene and the *apr* gene as a selective marker in *Escherichia coli* (ampicillin resistance). Plasmid diagrams were constructed using Vector NTI software (Invitrogen).
LDH activity and transcription of the C. bescii LDH gene were measured in the P. furiosus LAC strain over the growth temperature range from 72 to 83°C. Transcription of the ldh gene from C. bescii (Cbes-ldh) is controlled by the P_cipA promoter, and the corresponding CipA protein was reported previously to be produced at 72°C (15), although no data are available on its expression at other temperatures. While the growth rate of P. furiosus LAC drastically increases with increasing temperature, the highest relative Cbes-ldh mRNA level was found in cultures grown at 72°C (Fig. 5A). In addition, the highest specific LDH activities were detected in cultures grown in the 72 to 75°C range (Fig. 5B). Obviously, the promoter induces transcription, and this leads to protein production at those low temperatures and to reasonable amounts and activities of the recombinant protein, even though the culture itself exhibited relatively poor growth (Fig. 5A).

To confirm that producing C. bescii LDH in P. furiosus at 72°C was comparable to producing the enzyme in C. bescii, we determined the properties of the recombinant LDH produced in P. furiosus with those of the native LDH produced in C. bescii (Fig. 5C and D). Both forms of the enzyme had temperature optima near 75°C, close to the optimal growth temperature of C. bescii (18), and both forms had only barely detectable activity above 90°C, which is above the maximal growth temperature of C. bescii (90°C). Moreover, both forms of the enzyme had a relatively long half-life of about 5 h at the temperature optimum (75°C). Such stability is comparable to that of the most thermostable LDH previously reported, the enzyme from Thermotoga maritima, an organism that has growth properties similar to that of C. bescii (T_{opt} of 80°C) (20).

In terms of temperature-dependent bioprocessing, a useful approach would be to grow P. furiosus to a high cell density under conditions that are nearly optimal for growth in the absence of heterologous gene expression and then cold shock the culture for bioproduction generation as a result of heterologous gene expression. The LAC strain was grown at 94°C, conditions known not to lead to detectable C. bescii LDH activity or detectable amounts of ldh mRNA, to a cell density of 2 × 10^8 ml^{-1}, and the culture was rapidly cooled to 72°C (over 10 min). At this point, lactate could not be detected in the culture medium. However, 5 h after the switch, mRNA corresponding to C. bescii ldh was detected and lactate was measured in the growth medium (Fig. 4B). Moreover, the concentration of both ldh mRNA (relative to the level of the gamma subunit of the constitutively expressed pyruvate-ferredoxin oxidoreductase) and lactate increased over the following 25 h (Fig. 4B), leading to the production of approximately 3 mM lactate. Cells contained C. bescii LDH with a specific activity of 1.9 ± 0.6 U mg^{-1}. The latter value is comparable to those determined with cells grown in batch culture at 72°C (Fig. 1B), showing that cold shock bioproduct generation is a valid experimental approach.

**DISCUSSION**

We have demonstrated that a microorganism (in this case, from the domain Archaea) that grows optimally near 100°C transcribes mRNA and produces the corresponding enzyme, LDH, from another microorganism (in this case, from the domain Bacteria) that grows optimally at 78°C but does so only under the conditions where the foreign protein shows significant catalytic activity, namely, below 80°C. The activity of the heterologously expressed LDH in P. furiosus might be the result of processes at both the RNA and protein level. First, the relative ldh mRNA level increased due to the cold-induced promoter, with an upregulation about 10-fold at 72°C. Although cold-responsive promoters have been previ-
ously reported in mesophilic bacteria, they were utilized to facili-
tate protein folding at low temperature (reference 21 and refer-
ences therein) rather than to exploit temperature induction for
biotechnological purposes such as biofuel production. Second,
the stability of the protein and its activity decreased with increas-
ing temperature above 80°C. Interestingly, only two LDHs have
been previously characterized from thermophiles, and they are
homooligomeric enzymes (20, 22). The finding that
\textit{C. bescii} LDH produced in \textit{P. furiosus} and \textit{C. bescii} were similarly thermostable
suggests that the \textit{P. furiosus} version was correctly assembled into
its multimeric form.

Recombinant production of the \textit{C. bescii} LDH represents the
first bacterial protein to be expressed in a hyperthermophilic mi-
croorganism from the domain \textit{Archaea} and one of the first heter-
ologously expressed proteins in archaea in general (16, 17, 23). It
provides interesting options for the future production of other
bacterial proteins, particularly ones involved with lignocellulosic
biomass degradation, since an archaeon that can degrade crystal-
line cellulose has yet to be reported (2, 3). Indeed, the lactate-
producing strain described here offers a potential platform to en-
hance the temperature limit for lactate production from
lignocellulosic substrates, a process of industrial interest (24).

\textit{P. furiosus} has therefore been metabolically engineered to
change its end products of fermentation without the need for the
addition of any chemical inducer, and thus any indirect impact on
its metabolism or the accumulation of inducer products. More-
over, we demonstrate that temperature is an effective means of
regulation even using cells grown rapidly to high cell density, par-
ticularly since the corresponding mRNA, enzyme activity, or
product (lactate) could not be detected until the temperature was
lowered. The unusual cold shock response of \textit{P. furiosus} could be a
powerful tool for biotechnological applications.

\begin{figure}[h]

\caption{(A and B) Lactate production (blue squares), acetate production (green triangles), cell density (red circles), and relative mRNA fold expression levels (broken lines) in 15-liter fermentor cultures of \textit{P. furiosus} LAC. One culture was grown at 72°C (A), while another culture was grown at 94°C and rapidly cooled to 72°C after a cell density of \(1.5 \times 10^8\) was reached (indicated by the black arrow) (B). After the temperature switch, higher mRNA levels for the heterologous
gene \textit{Cbes-ldh}, high specific activity of lactate dehydrogenase, and a high rate of lactate formation were observed.}
\end{figure}
MATERIALS AND METHODS

Strains and media. Pyrococcus furiosus strains used in this study are listed in Table 1. In the transformation experiments, P. furiosus (DSM 3638) was cultured with 5 g liter⁻¹ maltose as the primary electron donor on liquid and solid complex medium as previously described (8). In all other experiments, the same medium was used, except that it contained no casein, but a yeast extract concentration of 2 g liter⁻¹. Genes were subcloned into pET22b(+) or pET22b(−) plasmids (Novagen), and expression constructs were introduced into E. coli strains BL21 and C. bescii. For the heterologous expression of the putative l-lactate dehydrogenase of P. furiosus (native LDH) and P. furiosus strain LAC (recombinant LDH) grown at 75°C and harvested in the stationary phase. Values given are averages ± SD of three independent biological cultures (B) or three independent enzymatic measurements (D), unless denoted otherwise. n.d., not determined.

Genetic manipulations. Extraction of DNA from C. bescii was performed by the method of Zhou et al. (26). Extraction of DNA from P. furiosus, transformation of P. furiosus, and selection of genetically modified strains were performed as previously described (8). P. furiosus COM1 served as the parent strain for genetic manipulations. A deletion of the pyruvyl-dependent arginine decarboxylase (pdaD) gene (PF1623) was achieved by homologous recombination with the P_pdaDpyrF cassette (11). The resulting strain, P. furiosus ΔpdaD strain, was used as the parent strain for the heterologous expression of the putative l-lactate dehydrogenase of C. bescii (Cbes-ldh). Cbes-ldh was amplified by PCR using the primer set Cbes1918-F (F stands for forward) and Cbes1918-KpnI-R (R stands for reverse). The cold-induced promoter P_cipA was amplified from genomic DNA from P. furiosus DSM3638 with the primer set P_cipA-SacII-F and P_cipA-Cbes1918-R. Finally, the fusion product P_cipA_Cbes1918 was obtained by overlapping PCR using both products from the PCRs above and the primers P_cipA-SacII-F and Cbes1918-KpnI-R. The fusion product was introduced between the SacI site and the KpnI site of the pdaD cassette into the chromosome was achieved by PCR with the primer set PF1623L-F and PF1623R-R located upstream and downstream of the cassette and subsequent sequencing. All primers used for PCR are listed in Table 2.

Preparation of cell extracts and enzyme assays. P. furiosus and C. bescii cells were harvested by centrifugation for 10 min at 6,000 × g. C. bescii cells were resuspended in 50 mM Tris (pH 8) and disrupted by sonication (five times, 2 min each time, maximum of 36 W and discontinuous operation at 50% of time). The P. furiosus cells were lysed by osmotic shock in 50 mM Tris HCl (pH 8.0) and 2 mM sodium dithionite. The lysis buffer contained 50 mg/ml DNase I (Sigma) to decrease the viscosity of the protein extract. Fractionation of the resulting protein extract into the soluble (cytoplasmic) fraction and the membrane fraction was achieved by ultracentrifugation at 100,000 × g for 3 h. Protein concentrations were determined from aliquots of each fraction.

Preparation of cell extracts and enzyme assays. P. furiosus and C. bescii cells were harvested by centrifugation for 10 min at 6,000 × g. C. bescii cells were resuspended in 50 mM Tris (pH 8) and disrupted by sonication (five times, 2 min each time, maximum of 36 W and discontinuous operation at 50% of time). The P. furiosus cells were lysed by osmotic shock in 50 mM Tris HCl (pH 8.0) and 2 mM sodium dithionite. The lysis buffer contained 50 mg/ml DNase I (Sigma) to decrease the viscosity of the protein extract. Fractionation of the resulting protein extract into the soluble (cytoplasmic) fraction and the membrane fraction
was achieved by ultracentrifugation at 100,000 \times g for 1 h. The membrane fraction was washed once with 50 mM Tris (pH 8.0) in order to minimize contamination with soluble proteins. Lactate dehydrogenase (LDH) (EC 1.1.1.27) activity was determined photometrically by the oxidation of NADH (340 nm) concomitant with lactate formation according to the following chemical equation: NADH + pyruvate + H^+ \rightarrow NAD^+ + lactate. The assays were performed aerobically in closed glass cuvettes at 75°C, which contained 2.5 mM NADH in 50 mM sodium phosphate buffer (pH 7.0). The rate of nonspecific oxidation of NADH was determined before the reaction was started by the addition of 5 mM pyruvate. As internal controls for the quality of the P. furiosus protein extracts, glutamate dehydrogenase (GDH) (EC 1.4.1.2) activity was routinely measured by the formation of NADP (340 nm) according to the following chemical equation: NADP^+ + glutamate + H_2O \rightarrow 2-oxoglutarate + NH_4^+ + NADH. The GDH assay was the same as for LDH except that NADH was exchanged for NADP^+ (0.25 mM), and pyruvate was exchanged for glutamate (5 mM). The protein content of the cell-free extracts were determined by the method of Bradford (28).

RNA extraction and quantitative PCR. Cells were harvested for RNA extraction in the late exponential phase of the growth curve unless noted otherwise. Cells were centrifuged for 10 min at 6,000 \times g and frozen until further processing. RNA was extracted using the Absolute RNA miniprep kit (Agilent Technologies), including a DNA digestion step with Turbo DNase (Ambion, Austin, TX) for 30 min at 37°C. cDNA was prepared using the Affinity Script cDNA synthesis kit (Agilent Technologies) and was used as an internal control to calculate the relative mRNA level of Ches-ldh. Primers for qRT-PCR were designed using the VectorNTI software (Invitrogen). The amplicon sizes were 194 bp and 267 bp for Ches-ldh and PF0971, respectively. Primers were tested for nonspecific products, and all experiments included controls without the addition of reverse transcriptase in the cDNA synthesis step to test for DNA contamination. The comparative cycle threshold method was used to analyze the resulting data, which are expressed as a ratio of gene expression change (older method was used to analyze the resulting data, which are expressed as fold change) unless noted otherwise. Cells were centrifuged for 10 min at 6,000 \times g and frozen until further processing. RNA was extracted using the Absolute RNA miniprep kit (Agilent Technologies), including a DNA digestion step with Turbo DNase (Ambion, Austin, TX) for 30 min at 37°C. cDNA was prepared using the Affinity Script cDNA synthesis kit (Agilent Technologies). All quantitative reverse transcription-PCRs (qRT-PCRs) were performed with an Mx3000P instrument (Stratagene), using the Brilliant Sybr green QPCR master mix (Agilent Technologies). The gamma subunit of the constitutively transcribed gene encoding the pyruvate-ferredoxin oxidoreductase (29) (PF0971) was used as an internal control for the quality of the RNA extraction and quantitative PCR. The primers used in this study are listed in Table 2.
