Abstract—Neural networks have often been described as black boxes. A generic neural network trained to differentiate between kittens and puppies will classify a picture of a kumquat as a kitten or a puppy. An autoencoder watchdog screens trained classifier/regression machine input candidates before processing, e.g. to first test whether the neural network input is a puppy or a kitten. Preliminary results are presented using convolutional neural networks and convolutional autoencoder watchdogs using MNIST images.

I. INTRODUCTION
Akin to principle component analysis [23], autoencoders can implicitly learn by the estimation of a lower dimensional manifold on which training data lives [32], [33]. The feature space dimension is determined by the cardinality of the autoencoder’s input and output. The dimension of the manifold is dictated by the size of the bottleneck layer (or waist) of the autoencoder. Representative test data presented to a properly trained autoencoder will generate an output similar to the input.

More generally, the root mean square error (RSME) between the autoencoder input and output can be viewed as the rough distance measurement between the autoencoder input and the training data manifold in the feature space. For this reason, autoencoders can be used in novelty detection [10], [30], [32].

One could train a neural network on three outputs: kittens, puppies and all other images that are not kittens or puppies. One challenge to this approach is that the set of images that do not contain kittens or puppies is prohibitively large. Work done by Abbasi and DeVries [1], [7] suggest strategies to work around the need for these large datasets.

Use of an autoencoder watchdog is a more reasonable solution [30], acting as a novelty (or anomaly) detector which protects the classifier neural network from fraudulent inputs. The autoencoder generates the manifold of data points that represent kittens and puppies. Any image lying far from the manifold is not a kitten or a puppy.

A data point that lies close to the manifold need not be a kitten or a puppy. Another image may coincidently lie on the manifold. In anomaly detection, a flag raised by the autoencoder is therefore sufficient for detecting anomalies but is not necessary for detecting outliers.

II. BACKGROUND
Interest in, and the application of neural networks [27] continues to expand at a rapid rate and cover a variety of tasks of varying complexities. Yadav et al present an excellent introduction to the history of neural networks [40]. Autoencoder neural networks are of particular interest in watchdog novelty detection. They have been used in a variety of different applications and may be implemented in a variety of different ways. For example, Baur [4] has demonstrated anomaly detection in medical scans, whereas Alvernaz [3] explored the ability to visually analyze and learn to play complex videogames. Vu [36] has investigated anomaly detection using adversarial autoencoders, while Lore [14] has reported their use in low-light image enhancement applications.

Autoencoders are useful for denoising various types of data, from audio to medical images. Work done by Gondara [9] and Vincent [35] provide excellent examples of the these denoising techniques. Autoencoders have been also been used in generative networks, as described by Mescheder [19]. Most commonly used in generative adversarial networks, or GANs, autoencoders have shown remarkable capabilities in generating images from noise. Work done by Zhifei Zhang [44], Zijun Zhang [45], Huang [11], and Ranjan [26] have shown some impressive generative capabilities across multiple spectrums, from grayscale digits to 3D face images. Work done by Luo [16] demonstrates...
different techniques based on the combination of variational autoencoders (VAEs) and GANs. Work done by Lu [15], Xia [38], and Qi [24] have demonstrated various applications beyond denoising and generation, highlighting the flexibility and useability of autoencoders.

As the artificial neural network field continues to grow and new tools continue to be developed, it is becoming easier to develop neural networks without a deep understanding of the driving principles. These new tools (eg TensorFlow, PyTorch, Keras, FastAI) lead to many neural networks being generally treated as black boxes. Our interest in these black boxes, as described by Alain et al [2], is less aimed at diving into the inner workings and attempting to demystify them, but rather to develop a technique that may be used with both existing and newly developed neural networks to address the uncertainty born of opaque neural networks. While there have been several attempts at diving in to the understanding of neural networks, such as the work done by Schartz [29], Zeiler [42], Martin [22] and Markopoulos [21], much of today’s end products are assumed to be “black boxes”.

While there is no shortage of neural network structures and applications, our research focuses on convolutional neural networks (CNN’s) and autoencoders. CNN’s have demonstrated impressive performance in the classification and generation of data. As an example, Zhang [43] provides an excellent introduction to the concept of text understanding, paralleling the interpretation of hand written digits. Bhatnagar [5] demonstrates the classification capabilities of CNNs on clothing items. Other work [6], [31] further details these capabilities while introducing new approaches for network design and performance optimization.

III. THE NEURAL NETWORK WATCHDOG

The neural network watchdog is a tool to determine a neural network’s output validity. This is achieved by using the generative component of the autoencoder to reconstruct the input data and calculating a difference score. The difference score is then compared to a threshold that determines data validity. In this paper, we build on the use of autoencoders to create the generative component of the watchdog. For our differing component, the root mean square error (RMSE: the square root of the sum of the squares) is calculated and comparing against a fixed threshold. Below are descriptions of the classification and watchdog autoencoder networks, the training and evaluation datasets, and the classifier and watchdog performance analysis.

A. Network Structures

For the viability study, both our classifier and autoencoder are CNN’s. Work by LeCun [13], Ng [20], and Meng [18] provide an excellent foundation for designing such networks. The MNIST handwritten digit image dataset is used to train the neural network and its watchdog autoencoder.

1) The Autoencoder Watchdog: The CNN autoencoder is comprised of a convolutional encoder network, coupled with a decoding network. The encoder structure is shown in Figure. [1]

The decoding structure mirrors the encoder structure, as shown in Figure. [2]. The encoder and decoder structures are stacked to form the autoencoder. The resulting structure is shown in Figure. [3].

2) Convolutional Neural Network Structure: As demonstrated by Ciresan [6], Tabik [31], and Bhatnagar [5], CNNs have shown impressive image classification capabilities. Our convolutional neural network classifier, described in Figure 4, is modeled after an example CNN provided by Geron in [8].

B. Training the Networks

1) Training and evaluation datasets: With the structures of the networks established, we turn to identifying the training and evaluation datasets. The training data comes entirely from the MNIST handwritten digit dataset, and consists of 60,000 training and 10,000 test images evenly split across 10 classes of digits, 0-9. The evaluation dataset is augmented to include the fashion MNIST dataset test images. First introduced by Xiao in 2017 [39], the fashion MNIST
Fig. 2: The decoder, which mirrors the encoder network. By matching the encoder’s structure, the decoder can reproduce data structurally identical to the encoder input using the lower dimension representation created by the encoder.

Fig. 3: The autoencoder, comprised of the encoder and decoder, allows the watchdog to generate input data based on the representations created at the waist layer.

dataset is comprised of 70,000 total images, evenly distributed across 10 classes of different clothing types. These datasets were chosen due to their identical size, allowing for their easy use in the training and testing of both the autoencoder and classifier without modification. Both the autoencoder and the CNN were trained on 50,000 digit image dataset and validated on an additional 10,000 digit images from the training set. Examples of the training data are shown in Figures. 5a and 5b.

In order to evaluate the effectiveness of the classifier and its watchdog, three evaluation datasets are used. The evaluation datasets are the combination of test images from the digit and fashion image sets. Additional examples can be seen in Figures. 6a and 6b. Note that the evaluation images are separate from the training and validation datasets. The three datasets are as follows: in-distribution (digit images), out-of-distribution (fashion images), and mixed-distribution (both digit and fashion images).

1) 10,000 test images from the MNIST digit dataset, in-distribution data
2) 10,000 test images from the fashion MNIST dataset, out-of-distribution data
3) 20,000 test images resulting from the combination of the MNIST digit and fashion MNIST test datasets, mixed-distribution data

IV. EVALUATING THE NETWORKS

A. Evaluating the autoencoder

With the three evaluation datasets established, the performance of the autoencoder is examined. The MNIST digit and fashion MNIST datasets are passed through the autoencoder independently. The outputs of the autoencoder, examples of which can be seen in Figures 7 and 8, were then stored separately for additional analysis. The resulting generated images were then compared to their respective original images and the RMSE was calculated. In order to determine the range of values expected when calculating the RMSE, multiply the image size, 28x28x1 pixels, by the maximum pixel value, which has been normalized to values between 0 and 1. For this dataset, the range of RMSE values is between 0 and 28, with a RMSE of 0 representing a perfect match, and a RMSE of 28 representing a perfect mismatch. Based on our experimentation, the average RMSE value calculated for the MNIST digit dataset was approximately 2.4, and the average RMSE value calculated for the fashion MNIST dataset was approximately 7.9.

B. Performance of the watchdog

1) ROC curves and classification errors: In order to show the effectiveness of the watchdog, we produce receiver operator characteristic (ROC) curves. These curves show the tradeoff between the true positive vs. false positive rates. The rates are determined as:

\[
TPR = \frac{TP}{TP + FN}
\]

\[
FPR = \frac{FP}{FP + TN}
\]

, where:

- TP - True Positive = correct classification, the in-distribution inputs that are within the acceptance threshold
- FP - False Positive = incorrect classification, the out-of-distribution inputs are within the acceptance threshold
- FN - False Negative = incorrect classification, the out-of-distribution inputs are above the acceptance threshold
- TN - True Negative = correct classification, the in-distribution inputs are above the acceptance threshold

With the average RMSE values established, the next step is determining an appropriate threshold. Figure 9 shows the ROC curve for the watchdog autoencoder.
This curve is the evaluation of the watchdog autoencoder based on its ability to separate the in-distribution digit images, or true positives, from out-of-distribution fashion images, or false positives.

2) Monitoring the classifier with the watchdog autoencoder: The value of adding the autoencoder watchdog to the mixed-distribution dataset can be seen in Figure 10 where the guarded mixed-distribution dataset has better performance than the unguarded mixed-distribution. As a point of reference, the ideal scenario, data contained only in the in-distribution dataset, has been included in Figure 10. As we have shown, the results from the watchdog produce a more accurate true positive vs. false positive rate, and a more vertical ROC curve, when compared to the individual dataset performance.

Along with the ROC curves, an interesting metric to note is the number of unrecognized images that have been detected in the dataset. The number of unrecognized images and the unrecognized image ratio, as seen in Figure 11, can be used as tools to help determine a final threshold value when designing and developing watchdog guarded networks.

V. CONCLUSION

An initial proof of concept neural network watchdog is proposed to help improve the performance of classifiers on various datasets. The approach is also transparently applicable to regression neural networks. The choice of RMSE threshold is ultimately determined by the desired detection versus false alarm tradeoff. Alternately, the RMSE can be used to inform users of a measure of closeness of an input to the manifold of the watchdog autoencoder defined in-distribution manifold in feature space.
