ABSTRACT

We propose a methodology to perform a self-consistent analysis of the physical properties of the emitting gas of HII galaxies adequate to the data that can be obtained with the XXI century technology. This methodology requires the production and calibration of empirical relations between the different line temperatures that should supersede currently used ones based on very simple, and poorly tested, photoionization model sequences.

As a first step to reach these goals we have obtained simultaneous blue to far red longslit spectra with the William Herschel Telescope (WHT) of three compact HII galaxies selected from the Sloan Digital Sky Survey (SDSS) Data Release 2 (DR2) spectral catalog using the INAOE Virtual Observatory superserver. Our spectra cover the range from 3200 to 10500 Å, including the Balmer jump, the [Oii] λλ3727,29 Å lines, the [Siii] λλ9069,9532 Å doublet as well as various weak auroral lines such as [Oiii] λ4363 Å and [Siii] λ6312 Å.

For the three objects we have measured at least four line temperatures: T([Oiii]), T([Siii]), T([Oii]) and T([Sii]) and the Balmer continuum temperature T(Bac). These measurements and a careful and realistic treatment of the observational errors yield total oxygen abundances with accuracies between 5 and 9%. These accuracies are expected to improve as better calibrations based on more precise measurements, both on electron temperatures and densities, are produced.

We have compared our obtained spectra with those downloaded from the SDSS DR3 finding a satisfactory agreement. The analysis of these spectra yields values of line temperatures and elemental ionic and total abundances which are in general agreement with those derived from the WHT spectra, although for most quantities they can only be taken as estimates since, due to the lack of direct measurements of the required lines, theoretical models had to be used whose uncertainties are impossible to quantify.

The ionization structure found for the observed objects from the O+/O2+ and S+/S2+ ratios points to high values of the ionizing radiation, as traced by the values of the “softness parameter” η which is less than one for the three objects. The use of line temperatures derived from T([Oiii]) based on current photoionization models yield for the two highest excitation objects, much higher values of η which would imply lower ionizing temperatures. This is however inconsistent with the ionization structure as probed by the measured emission line intensities.

Finally, we have measured the T(Bac) for the three observed objects and derived temperature fluctuations. Only for one of the objects, the temperature fluctuation is significant and could lead to higher oxygen abundances by about 0.20 dex.

Key words: galaxies: fundamental parameters - galaxies: starburst - galaxies: abundances - galaxies: temperature – ISM: abundances – HII regions: abundances
1 INTRODUCTION

Hii galaxies are low mass irregular galaxies with, at least, a recent episode of violent star formation (Melnick, Terlevich & Eggleton 1985; Melnick, Terlevich & Moles 1985) concentrated in a few parsecs close to their cores. The ionizing fluxes originated by these young massive stars dominate the light of this subclass of Blue Compact Dwarf galaxies (BCDs) which show emission line spectra very similar to those of giant extragalactic Hii regions (GEHRs; Sargent & Searle 1970; French 1980). Therefore, by applying the same measurement techniques as for Hii regions, we can derive the temperatures, densities and chemical composition of the interstellar gas in this type of generally metal-deficient galaxies. In some cases, it is possible to detect in these objects, intermediate-to-old stellar populations which have a more uniform spatial distribution than the bright and young stellar populations associated with the ionizing clusters (Schulte-Ladbeck et al. 1998). This older population produces a characteristic spectrum with absorption features which mainly affect the hydrogen recombination emission lines (Díaz 1988), that is the Balmer and Paschen series in the spectral range of interest. In some cases, the underlying stellar absorptions can severely affect the ratios of Hi line pairs and hence the determination of the reddening constant (C(Hβ)). They must therefore be measured with special care (see discussion in §3).

A considerable number of the blue objects observed at intermediate redshifts seem to have properties (mass, R_e, velocity width of the emission lines) similar to local Hii galaxies (Koo et al. 1994, 1997; Guzmán et al. 1998, 1998). In particular, those with σ < 65 km s^{-1} follow the same σ − L_B and L_Hβ relation as seen in Hii galaxies (Melnick et al. 2000; Mas-Hesse et al. 2003; Terlevich et al. 2003; Siegel et al. 2003). Similar conclusion is drawn from recent studies on Lyman Break galaxies that also suggest that strong narrow emission line galaxies might have been very common in the past (e.g. Pettini et al. 2000, 2001; Ellison et al. 2001). To detect possible evolutionary effects like systematic differences in their chemical composition, accurate and reliable methods for abundance determination are needed.

This is usually done by combining photoionization model results and observed emission line intensity ratios. There are several major problems with this approach that limit the confidence of present results. Among them: the effect of temperature structure in multiple-zone models (Pérez-Montero & Díaz 2003); the presence of temperature fluctuations across the nebula (Peimbert 2003); collisional and density effects on ion temperatures (Luridiana et al. 1999, Pérez-Montero & Díaz 2003); the presence of neutral zones affecting the calculation of ionization correction factors (ICFs; Peimbert et al. 2002); the ionization structure not adequately reproduced by current models (Pérez-Montero & Díaz 2003); ionization vs. matter bounded zones, affecting the low ionization lines formed in the outer parts of the ionized regions (Castellanos, Díaz & Terlevich 2002). On the other hand, the understanding of the age and evolutionary state of Hii galaxies require the use of self-consistent models for the ionizing stars and the ionized gas. However, model com-
puted evolutionary sequences show important differences with observations \cite{Stasinska&Izotov2003}, including: (a) \Heii is too strong in a substantial number of objects as compared to model predictions; (b) \[OIII]/Hβ vs. \[OII]/Hβ and \[OII]/Hβ vs. \[OIII]/Hβ are not well reproduced by evolutionary model sequences in the sense that predicted collisionally excited lines are too weak compared to observations; (c) there is a large spread in the \[NII]/[OII] values (more than an order of magnitude) for galaxies with the same value of (\[OIII]+\[OII])/Hβ in the metallicity range from 8 to 8.4 (see e.g. Pérez-Montero & Díaz 2005).

Substantial progress toward solving the problems listed above has to come from the accurate measurement of weak emission lines which will allow to derive \[OII], \[SII] and \[NeIII] temperatures and densities allowing to constrain the ionization structure as well as Balmer and Paschen discontinuities which will provide crucial information about the actual values of temperature fluctuations. It is possible that these fluctuations produce the observed differences between the abundances relative to hydrogen derived from recombination lines (RLs) and collisionally excited lines (CELS) when a constant electron temperature is assumed \cite{Peimbert1967,Peimbert&Costero1962,Peimbert1971}. These discrepancies have been observed in a good sample of objects, such as galactic \HII regions \cite[e.g.][]{EstebanJ2004, Garcia-Rojas2005, Tsamis&Pequignot2003} and references therein), \HII regions in the Magellanic Clouds \cite[e.g.][]{Peimbert&Costero1962, Peimbert2003, Tsamis&Pequignot2003} and references therein), extragalactic \HII regions \cite[e.g.][]{Peimbert2003, Guseva2006, Peimbert&Costero1962, Peimbert2003, Tsamis&Pequignot2003} and references therein) and planetary nebulae \cite[e.g.][]{Rubin2002, Wesson2005, Liu2006, Liu2008, Peimbert2006} and references therein). Likewise, there are relatively recent theoretical works that study the possible causes of these discrepancies in abundance determinations using photoionization models of different complexity \cite[e.g.][]{Stasinska&Izotov2003, Jamet2005, Tsamis&Péquignot2003} and references therein).

Unfortunately most of the available starburst and \HII galaxy spectra have only a restricted wavelength range (usually from about 3600 to 7000 \AA) and do not have the adequate S/N to accurately measure the intensities of the weak diagnostic emission lines. Even the Sloan Digital Sky Survey (SDSS) spectra \cite{Stoughton2002} do not cover simultaneously the \[OII] \lambda 3727,29 and the \[SII] \lambda 9069 \AA lines. We have therefore undertaken a project with the aim of obtaining a database of top quality line ratios for a sample that includes the best objects for the task. The data is collected using exclusively two arm spectrographs in order to guarantee both high quality spectrophotometry in the whole spectral range from 3500 to 10500 \AA and good spectral and spatial resolution. In this way we will be in a position to vastly improve constraints on the photoionization models including the mapping of the ionization structure and the measurement of temperature fluctuations about which very little is known.

In this first work we present observations of three \HII galaxies selected from the SDSS. Details regarding the selection of the objects as well as the observations are given in Section 2. Section 3 presents the results including line measuring techniques. The methodology for the derivation of gaseous physical conditions and elemental abundances is presented in Sections 4 and 5 respectively. The discussion of our results, including a detailed comparison with the SDSS data is presented in Section 6. Finally, Section 7 summarizes the main conclusions of our work.

2 OBSERVATIONS AND DATA REDUCTION

2.1 Object selection

SDSS constitutes a great base for statistical studies of the properties of galaxies. At this moment, the Fourth Data Release \cite[DR4]{1}, the last one up to now, contains five band photometric data for about $18 \times 10^7$ objects and more than $6.7 \times 10^8$ spectra of galaxies, quasars and stars \cite{Adelman-McCarthy2006}. The spectroscopic data have a resolution \cite[R] of 1800-2100 covering a spectral range from 3800 to 9200 \AA, with a single 3 arcsec diameter aperture. The SDSS data were reduced and flux-calibrated using automatic pipelines. However, when we selected our objects on July 2004, the DR2\cite{2} was just available. Both data releases, DR2 and DR4, contain the same type of objects observed in the same five photometric bands and using the same spectroscopic configuration. DR2 has photometric data for over 88 million unique objects and about $3.7 \times 10^5$ spectra \cite{Abazajian2004}. All the objects belonging to one data release are also included in the next ones, but some objects could have been re-calibrated or re-observed somehow. Using the implementation of the SDSS database in the INAOE Virtual Observatory superserver\cite{3}, we have selected from the whole SDSS DR2 the brightest nearby narrow emission line galaxies with very strong lines. Our selection parameters were:

- Equivalent width of \Halpha $> 50$ \AA,
- $1.2 < \sigma(\Halpha) < 7$ \AA,
- redshift, $z < 0.2$ and
- \Halpha flux, $F(\Halpha) > 4 \times 10^{-14} \text{erg cm}^{-2} \text{s}^{-1} \text{\AA}^{-1}$.

This preliminary list was then processed using BPT \cite{Baldwin1981} diagnostic diagrams to remove AGN-like objects.

The final list consists of about 200 bonafide bright \HII galaxies. They show spectral properties indicating a wide range of gaseous abundances and ages of the underlying stellar populations \cite{Lopez2005}.

From this list, the final set was selected by further restricting the sample to the largest \Halpha flux and highest S/N objects.

From the 10 brightest of the final set we selected three \HII galaxies to be observed in our one single night observing run. This final selection was made based on the relative positions of the sources in the sky allowing to optimize the observing time. The journal of observations is given in table\cite{4} and the photometric characteristics of the objects are listed in table\cite{5}. Subsequently we have used the explore tool\cite{6} implemented in the DR3\cite{Abazajian2005}, which was

\end{enumerate}

\normalsize
set-up configuration is 0.2 arcsec for both spectral ranges.

The pixel size for this pointings with the ‘SLOW’ CCD speed. The pixel size for this observation we have taken the observations at parallactic angle to avoid effects of differential refraction in the UV. The instrumental discontinuity and the nebular lines of [O\textsc{iii}] λ4363, [S\textsc{ii}] λλ4068, 6717 and 6731, and [S\textsc{iii}] λ6312.

Several bias and sky flat field frames were taken at the beginning and at the end of each night in both arms. In addition, two lamp flat fields and one calibration lamp exposure were performed at each telescope position. The calibration lamp used was CuNe+CuAr. The images were processed and analyzed with IRAF\textsuperscript{6} routines in the usual manner. The procedure includes the removal of cosmic rays, bias subtraction, division by a normalized flat field and wavelength calibration. Typical wavelength fits were performed using 30-35 lines in the blue and 20-25 lines in the red and polynomials of second to third order. These fits have been done at 117 different locations along the slit in each arm (beam size of 10 pixels) obtaining rms residuals between ~0.1 and ~0.2 pix.

In the last step, the spectra were corrected for atmospheric extinction and flux calibrated. For the blue spectra, four standard star observations were used, allowing a good spectrophotometric calibration with an estimated accuracy of about 5%. Unfortunately, only one standard star could be used for the calibration of the red spectra. Nevertheless, after flux calibration, in the overlapping region of the spectra taken with each arm, the agreement in the average continuum level was good.

### 2.2 Observational details

The blue and red spectra were obtained simultaneously using the ISIS double beam spectrograph mounted on the 4.2m William Herschel Telescope (WHT) of the Isaac Newton Group (ING) at the Roque de los Muchachos Observatory, on the Spanish island of La Palma. They were acquired on July the 18th 2004 during one single night observing run and under photometric conditions. EEV12 and Marconi2 detectors were attached to the blue and red arms of the spectrograph, respectively. The R300B grating was used in the blue covering the wavelength range 3200-5700 Å (centered at λ = 4450 Å), giving a spectral dispersion of 0.86 Å/pixel\textsuperscript{−1}. On the red arm, the R158R grating was mounted providing a spectral range from 5500 to 10550 Å (λ = 8025 Å) and a spectral dispersion of 1.64 Å/pixel\textsuperscript{−1}. In order to reduce the readout noise of our images we have taken the observations with the ‘SLOW’ CCD speed. The pixel size of this set-up configuration is 0.2 arcsec for both spectral ranges. The slit width was ~0.5 arcsec, which, combined with the spectral dispersions, yielded spectral resolutions of about 2.5 and 4.8 Å FWHM in the blue and red arms respectively. All observations were made at parallactic angle to avoid effects of differential refraction in the UV. The instrumental configuration, summarized in table 3, was planned in order to cover the whole spectrum from 3200 to 10550 Å providing at the same time a moderate spectral resolution. This guarantees the simultaneous measurement of the Balmer discontinuity and the nebular lines of [O\textsc{ii}] λλ3727,29 and [S\textsc{ii}] λλ6966,9532 Å at both ends of the spectrum, in the very same region of the galaxy. A good signal-to-noise ratio was also required to allow the detection and measurement of weak lines such as [O\textsc{ii}] λ4363, [S\textsc{ii}] λλ4068, 6717 and 6731, and [S\textsc{iii}] λ6312.

### 3 RESULTS

The WHT spectra of the observed galaxies with some of the relevant identified emission lines are shown in Figs. 1 and 2. Each figure is split into two panels, showing the blue (upper panel) and red (lower panel) spectral ranges.

The emission line fluxes were measured using the SPLOT task of IRAF and are listed for the three observed galaxies in tables 4 through 6. Column 1 of each table shows the wavelength and the name of the measured lines, as referred in García-Rojas et al. (2003). The observed emission line fluxes, $F(\lambda)$ (in units of H\textalpha flux = 1000) with their corresponding errors, are presented in column 2. The measured equivalent widths (EW) are listed in column 3.

We have used two different ways to integrate the flux of a given line: (1) in the case of an isolated line or two blended and unresolved lines the intensity was calculated integrating between two points given by the position of the local continuum placed by eye; (2) if two lines are blended, but they can be resolved, we have used a multiple gaussian fit procedure to estimate individual fluxes. Following García-Rojas et al. (2003), the observed emission line fluxes, $F(\lambda)$ (in units of H\textalpha flux = 1000) with their corresponding errors, are presented in column 2. The measured equivalent widths (EW) are listed in column 3.

(1994), Castellanos, Díaz & Terlevich (2002) and Pérez-Montero & Díaz (2003), the statistical errors associated with the observed emission fluxes have been calculated using the expression $\sigma = \sigma_1 \sqrt{N}$; where $\sigma$ is the error in the observed line flux, $\sigma_1$ represents the standard deviation in a box near the measured emission line and stands for the error in the continuum placement, $N$ is the number of pixels used in the measurement of the line flux, EW is the line equivalent width, and $\Delta$ is the wavelength dispersion in angstroms per pixel. There are several lines affected by bad pixels, internal reflections or charge transfer in the CCD, telluric emission lines or atmospheric absorption lines. These cause the errors to increase, and, in some cases, they are impossible to quantify. In these cases we do not include these lines in the tables nor in our calculations. The only exception is the emission line [SIII]$\lambda$9069 for SDSS J162410.11-002202.5 which is affected by the strong narrow water-vapor lines present in the $\lambda$9300 - 9500 wavelength region (Díaz, Pagel & Wilson 1985). We have listed the value of the measurement of this line in table 4, but all the physical parameters depending on its intensity were calculated using the theoretical ratio between this line and [SII]$\lambda$9532, [OIII]$\lambda$9069 $\approx 2.44 \times$ I(9532) (Osterbrock 1989). In some cases, these systems show some evidence of interaction among their components (Telles, Melnick & Terlevich 1997). For instance, HIz40, which was first classified as a compact emission line galaxy by Sargent (1970), when observed with enough spatial resolution showed to be the merge of two separate subsystems (Baldwin, Spinrad & Terlevich 1982). As a consequence, lines that should be resolved are blended in the spectrum of SDSS J002101.03+005248.1. Such is the case of Hα and [NII] $\lambda$6548 Å emission lines. We have resorted to the theoretical ratio, I(6584) $\approx 3 \times$ I(6548), to decontaminate the observed flux of Hα by the emission of [NII] $\lambda$6548 and to derive the electron temperature of [NII].

A conspicuous underlying stellar population is easily appreciable by the presence of absorption features that depress the Balmer and Paschen emission lines. The upper panel of Fig. 4 shows an example of this effect for the Balmer lines (H13 to H6) on an enlargement of the spectrum of SDSS J003218.60+150014.2, the object that presents the most relevant and appreciable absorption lines. The pseudo-
ing absorption on the measured emission line intensities, we are the same. In order to quantify the effect of the underlying stellar population, we assume the galactic extinction law of Miller & Mathews (1972) with $R_v=3.2$. $C(H\beta)$ was obtained in each case by performing a least square fit to the ratio between $F(\lambda)$ and $F(H\beta)$ to the theoretical values computed by Storey & Hummer (1995) using an iterative method to estimate $T_e$ and $n_e$ in each case. We have taken $n_e$ equal to $n([\text{Si} \ ii])$. Due to the large error introduced by the presence of the underlying stellar population (see discussion above) only the four strongest Balmer emission lines (H\alpha, H\beta, H\gamma and H\delta) have been taken into account. The values obtained for $C(H\beta)$ and their corresponding errors, considered to be the uncertainties of the least square fittings, are listed in tables 4, 5, and 6 for each of the observed objects.

The emission line intensities corrected for reddening, relative to H\beta ($I(\lambda)$), and their corresponding errors are listed in column 4 of tables 4, 5, and 6. The errors were obtained propagating in quadratures the observational errors in the emission line fluxes and the reddening constant uncertainties. We have not taken into account errors in the theoretical intensities since they are much lower than the observational ones. Finally, the values listed in Column 5 of the tables indicate the fractional error in the line intensities calculated as explained above. These errors vary from a few percent for the more intense nebular emission lines (e.g. [O\ii] $\lambda\lambda 4959,5007$, [S\ii] $\lambda\lambda 6717,6731$ or the strongest Balmer emission lines) to 10-16% for the weakest lines that have less contrast with the continuum noise (e.g. HeI $\lambda\lambda 3820,7281$, [Arv] $\lambda 4740$ or O\i $\lambda 8446$). For the auroral lines, the fractional errors are between ~3 and ~9%.

4 PHYSICAL CONDITIONS OF THE GAS

4.1 Electron densities and temperatures from forbidden lines

The physical conditions of the ionized gas, including electron temperatures and electron density, have been derived from the emission line data using the same procedures as in Pérez-Montero & Díaz (2003), based on the five-level statistical equilibrium atom approximation in the task TEMDEN, of the software package IRAF (De Robertis, Dufour & Hunt, 1987; Shaw & Dufour, 1995). The atomic coefficients used here are the same as in Pérez-Montero & Díaz (2003; see table 4 of that work), except in the case of O\i for which we have used the transition probabilities from Zeippen (1982) and the collision strengths from Pradhan (1976).

| T([SII])   | (I(6717A)+I(6731A))/(I(4068A)+I(4074A)) |
| T([NII])   | (I(6548A)+I(6584A))/I(5755A) |

which offer more reliable nebular diagnostics results for this species (Wang et al., 2004). We have taken as sources of error the uncertainties associated with the measurement of the emission-line fluxes and the reddening correction and we have propagated them through our calculations. Electron densities have been derived from the [SII] \( \lambda \lambda 6717 / 6731 \) A line ratio, which is representative of the low-excitation zone of the ionized gas. In all cases they were found to be lower than 200 particles per cubic centimeter, well below the critical density for collisional deexcitation. We have tried to derive the electron densities from the [ArIV] \( \lambda \lambda 4713 / 4740 \) A line ratio, by decontaminating the first one from the HeII contribution, but the derived density values had unacceptable errors due to their large and sensitive dependences on the emission line intensities and the errors of the observed fluxes.

Several electron temperatures for each spectrum have been measured: T([OIII]), T([OIII]), T([SII]), T([SII]) and T([NII]). The [NII] line at 5755 Å was not detected in the spectrum of SDSS J003218.60+150014.2 and therefore it was not possible to measure T([NII]) for this object. Both the [OIII] \( \lambda \lambda 7319, 7330 \) Å and the [NII] \( \lambda 5755 \) Å lines can have a contribution by direct recombination which increases with temperature. Using the calculated [OIII] electron temperatures, we have estimated these contributions to be less than 4% in all cases and therefore we have not corrected for this effect, although we have considered them when estimating the errors. The emission-line ratios used to calculate each temperature are summarized in table 6.

The derived electron densities and temperatures for the three observed objects are listed in columns 2, 4 and 6 of table 6 along with their corresponding errors.

4.2 Balmer temperature

The Balmer temperature depends on the value of the Balmer jump (BJ) in emission. To measure this value we have adjusted the continuum at both sides of the discontinuity (\( \lambda_{BD} = 3646 \) Å). Fig. 5 shows an example of the procedure for SDSS J003218.59+150014.2. The contribution of the underlying population (see Section 3) affect, among others, the hydrogen emission lines near the Balmer jump. The increase of the number of lines toward shorter wavelengths produces blends which tend to depress the continuum level to the right of the discontinuity and precludes the application of multi-gaussian component fittings. We have taken special care in the definition of this continuum by using a long baseline and spectral windows free of absorption lines. The uncertainties due to the presence of the underlying stellar population (dif-

![Figure 5](image-url)
different possible continuum placements) have been included in the errors of the measurements of the discontinuities. They are actually smaller than the error introduced by the fitting of stellar templates. Once the Balmer jump is determined from the ratio of the Balmer jump flux to the flux of the H11 Balmer emission line using equation (3) in Liu et al. (2001):

$$T(Bac) = 368 \times (1 + 0.259y^+ + 3.409y^{2+}) \left( \frac{BJ}{H1} \right)^{-3/2} K$$

where $y^+$ and $y^{2+}$ are the ionic abundances of singly and doubly ionized helium, He$^+/H^+$ and He$^{2+}/H^+$ (see §), respectively, and BJ is in ergs cm$^{-2}$ s$^{-1}$ Å$^{-1}$. The derived values for T(Bac) are also listed in table 8.

## 5 CHEMICAL ABUNDANCES

Ionic and total abundances of He, O, N, Ne, Ar and Fe are obtained as detailed below and given in tables 8 and 10. We have derived the chemical abundances of the different species using the stronger available emission lines detected in the analyzed spectra. The total abundances have been derived by taking into account, when required, the unseen ionization stages of each element, resorting to the most widely accepted ionization correction factors (ICF) for each species:

$$\frac{X}{H} = ICF(X^+)/\frac{X^{++}}{H^+}$$

### 5.1 Helium abundance

We have measured emission fluxes for 10 lines of HeI and HeII, although four of them are blended with another emission line and two are so weak that they cannot be used to derive the helium abundance with the necessary accuracy. We have therefore used the HeI λ4471, 5876, 6678 and 7065 Å, and HeII λ4686 Å lines to estimate the abundances of helium once and twice ionized respectively. These lines arise mainly from pure recombination, however they could have some contribution from collisional excitation as well as be affected by self-absorption and, if present, by underlying stellar absorption (see Olive & Skillman 2001, 2004 for a complete treatment of these effects). We have taken the electron temperature of [OIII] as representative of the zone where the He emission arises (i.e. $T(\text{HeII}) = T(\text{[OIII]}))$ and have used the equations given by Olive & Skillman to derive the He$^+/H^+$ value, using the theoretical emissivities scaled to Hβ from Smits (1996) and the expressions for the collisional correction factors from Kingdon & Ferland (1995). We have not taken into account, however, the corrections for collisional processes (three of the used helium lines have a negligible dependence on the electron temperature and the observed objects have low densities) and the underlying stellar population. The three galaxies show in their spectra the signature of the presence of WR stars by the blue ‘bump’ around λ4600 Å therefore we have to take care when measuring the emission line flux of HeII λ4686 Å (see Fig. 4). We have used equation (9) from Kunth & Sargent (1983) to calculate the abundance of twice ionized helium. Then, for the total abundance we have directly added the two ionic abundances:

$$\frac{He}{H} = \frac{He^+ + He^{2+}}{H^+}$$

The results obtained for each line and their corresponding errors are presented in table 8 along with the adopted value for He$^+/H^+$.

### 5.2 Ionic and total chemical abundances from forbidden lines

The oxygen ionic abundance ratios, O$^+/H^+$ and O$^{2+}/H^+$, have been derived from the [OIII] λλ3727,29 Å and [OIII] λλ4959, 5007 Å lines respectively. The simultaneous determination of $T([\text{OIII}])$ and $T([\text{OIII}])$ allows a more confident estimate of the total abundance of oxygen for which we have used the approximation:

$$\frac{O}{H} = \frac{O^+ + O^{2+}}{H^+}$$

Regarding sulphur, we have derived S$^+$ abundances using T([SII]) values and the fluxes of the [SII] emission lines at λλ6717, 6731 Å. In the same way, the abundances of S$^{2+}$
have been derived from the values of the directly measured \(T([\text{Sii}])\) and the near-IR \([\text{Sii}]\lambda 6509, 6584 \text{Å}\) lines. The total sulphur abundance has been calculated using an ICF for \(S^+ + S^{2+}\) according to Barker's (1980) formula, which is based on the photoionization models by Stasińska (1978):
Izotov et al. (2004) point out that this assumption can lead to an overestimate of Ne/H in objects with low excitation, where the charge transfer between \( O^{++} \) and \( H^0 \) becomes important. Nevertheless, in our case, it is probably justified given the high excitation of the observed objects.

The main ionization states of Ar in ionized regions are \( Ar^{2+} \) and \( Ar^{3+} \). The abundance of \( Ar^{2+} \) has been calculated by means of the emission line of \([Ar\text{II}]\lambda 7136\,\text{Å}\) assuming that \( T([Ar\text{II}]) \approx T([\text{SIII}]) \) (Garnett, 1992), while the ionic abundance of \( Ar^{3+} \) has been calculated under the assumption that \( T([Ar\text{V}]) \approx T([\text{OIII}]) \) and using the emission line of \([Ar\text{V}]\lambda 4740\,\text{Å}\). We could have used the blended emission line \([Ar\text{V}]+\text{HeI} \) at \( \lambda 4713\,\text{Å} \) subtracting the helium contribution. However, due to the relative abundance of these species and the signal-to-noise ratio of this blended line, we prefer not to estimate this ionic abundance with such a large error. The total abundance of Ar has been calculated using the ICF(\( Ar^{2+}+Ar^{3+} \)) given by Izotov et al. (1994) which, in turn, has been derived from the photo-ionization models by Stasińska (1990) as:

\[
\text{ICF}(Ar^{2+} + Ar^{3+}) = \left[ 0.99 + 0.091 \left( \frac{O^+}{O} \right) - 1.14 \left( \frac{O^+}{O} \right)^2 + 0.077 \left( \frac{O^+}{O} \right)^3 \right]^{-1}
\]

Finally, for iron we have used the emission line of \([Fe\text{II}]\lambda 4558\,\text{Å} \) and the electron temperature of \([\text{OIII}] \). We have taken the ICF(Fe\(^{2+}\)) from Rodríguez & Rubin (2004), which yields:

\[
\text{ICF}(Fe^{2+}) = \left( \frac{O^+}{O^{2+}} \right)^{0.09} \cdot \left[ 1 + \frac{O^{2+}}{O^+} \right]
\]

The ionic and total abundances for each observed element are presented in columns 2, 4 and 6 of table 10 along with their corresponding errors.

### 6 DISCUSSION

#### 6.1 Comparison with SDSS data

In order to compare our results with those provided by SDSS spectra, we have measured the emission line intensities and equivalent widths on the SLOAN spectra of the three observed objects in the same way as described in Section 3. In order to allow an easy comparison between the results on both sets of spectra, we have listed these values in columns 6 to 9 of tables 3, 4 and 6.

Strong emission line fluxes relative to \( H\beta \) measured on WHT and SDSS spectra differ by less than 10% for SDSS J003218.60+150014.2 and SDSS J162410.11-002202.5 and about 30% for SDSS J002101.03+005248.1. This is partially compensated by differences in the derived reddening constant so that reddening corrected emission line intensities relative to \( H\beta \) differ by less than 10% for the [OIII] \( \lambda \lambda 3727,29 \) Å line, about 15% for the weak [OIII] \( \lambda 4363\,\text{Å} \) and [SIII] \( \lambda 4632\,\text{Å} \) lines and only a few percent for the strong [OIII] \( \lambda 5007\,\text{Å} \) line. In fact, given the difference in aperture between both sets of observations, 0.5 and 3 arcsec for WHT and SDSS respectively, some differences are to be expected. While we have probably observed the bright cores of the galaxies where most of the light and present star formation is concentrated, the SDSS observations map a more extensive area which could include external diffuse zones. This is evidenced by the more conspicuous underlying stellar population detected in the WHT spectra which leads to lower values of the emission line equivalent widths.

The best agreement between the two sets of measurements is found for SDSS J003218.60+150014.2, which is probably the more compact object, as evidenced by the difference in the measured \( H\beta \) fluxes which is only a factor of 2 and the close agreement between the measured equivalent widths on the two spectra.

The SDSS spectra have been analyzed following the same methodology as explained in Sections 4 and 5 for the derivation of temperatures and abundances although, due to the different nature of the observations: different spectral coverage, signal-to-noise ratio and spectral resolution, some further assumptions had to be made. These refer mainly to the temperatures of the different ions. Regarding sulphur, the SDSS data do not reach the 9000-9600 Å range covered by the WHT spectra and therefore it was not possible to determine directly \( T([\text{SIII}]) \). The relation between \( T([\text{SIII}]) \) and \( T([\text{OIII}]) \) is reproduced in Fig. 4. The sample used for comparison is a compilation of published data for which measurements of the nebular and auroral lines of [OIII] and [SIII] exist, thus allowing the simultaneous determination of \( T([\text{OIII}]) \) and \( T([\text{SIII}]) \). The sample is listed in Tables 1 and 2 of Pérez-Montero et al. (2006; objects not marked with a superscript b, as explained in the text), where the reader can find all the information concerning the data. The dashed line in the plot corresponds to the theoretical relation based on the grids of photoionization models described in Pérez-Montero & Díaz (2005),

\[
T([\text{SIII}]) = 1.05 T([\text{OIII}]) - 0.08
\]

which differs slightly from the semi-empirical relation by Garnett (1992) mostly due to the introduction of the new atomic coefficients for \( S^{2+} \) from Tayal & Gupta (1999). The solid line in Fig. 4 corresponds to the actual fit to the data:

\[
T([\text{SIII}]) = (1.19 \pm 0.08) T([\text{OIII}]) - (0.32 \pm 0.10)
\]

The individual errors have not been taken into account in performing the fit. This fit is different from that found by Garnett (1992) that seems to reproduce well the M101 H\text{I}n region data analyzed by Kennicutt, Bresolin & Garnett (2003; KBG03). This is mostly due to the larger temperature baseline that we use. The object with the highest \( T([\text{SIII}]) \) in KBG03 is NGC5471A (12800°K); our sample includes high excitation H\text{I}n galaxies with \( T([\text{SIII}]) \) up to 24000°K, while including at the same time KBG03 sample. The introduction of the high excitation objects make the relation steeper and increases the error of the calibration. This illustrates the danger of extrapolating relations found for a restricted range of values. We have used our empirical calibration in order to obtain \( T([\text{SIII}]) \) for the SDSS spectra. The estimated errors introduced by the calibration are of the order of 12% for \( T([\text{SIII}]) \), i.e. between 1400 and 1500°K for the observed objects.

Likewise, the SDSS spectrum of J003218.60+150014.2 does not include the lines of [OIII] at \( \lambda \lambda 3727,29 \) Å and therefore it was not possible to derive \( T([\text{OIII}]) \). Again, we have reported to the model predicted relationship between \( T([\text{OIII}]) \) and \( T([\text{OIII}]) \) found by Pérez-Montero & Díaz (2003) that
tions had to be calculated using the intensity of the weak
coverage. This assumption is usually made in standard analy-

tions made and the theoretical models used are impossible to
calibrate and it is not possible to give an estimate of the
temperature introduced by the application of this procedure.

Finally, the Balmer continuum temperature could not
be calculated from the SDSS spectra due to lack of spectral
coverage.

Concerning abundances, the $\Sigma^{2+}/H^+$ abundance ra-
tios had to be calculated using the intensity of the weak
auroral [Siii] line at $\lambda$6312 Å and, in the case of SDSS
J003218.60+150014.2, the O$^+/H^+$ abundance ratio was de-

corresponding errors in the cases where they have been de-

tions from Stas\'inski\'a (1980; solid line) and Stas\'inski\'a ( 1990;
dashed-dotted line) are also shown. The temperatures are in
units of $10^4$ K.

For SDSS J003218.60+150014.2 the values we have ob-
tained for densities, temperatures and abundances from the
WHT and SDSS spectra are in excellent agreement within the
observational errors, as expected from the close agree-
ment between the measured emission line intensities. For
the other two objects, the agreement can be considered as
satisfactory, taking into account the difference in aperture
between both sets of observations.

6.2 Gaseous physical conditions and element
abundances

For the three observed objects we have been able to mea-
sure four electron temperatures: $T([\text{O}iii])$, $T([\text{O}i])$, $T([\text{S}ii])$ and $T([\text{S}iii])$. $T([\text{N}ii])$ has also been measured in two of the
objects. The good quality of the data has allowed to reach
accuracies of the order of 1% for $T([\text{O}iii])$, 3% for $T([\text{O}i])$
and 5% in the case of $T([\text{N}ii])$, $T([\text{S}ii])$ and $T([\text{S}iii])$. Figs. 8
and 9 show the range of the measured line temperatures
and electron density for objects SDSS J002101.03+005248.1,
SDSS J003218.60+150014.2 and SDSS J162410.11-002202.5,
respectively. The data for the latter two are very simi-
lar, although $T([\text{N}II])$ could not be measured for SDSS J003218.60+150014.2. The width of the bands correspond to one $\sigma$ error. In the two cases $T([\text{O}III])$ and $T([\text{S}II])$ overlap to some extent, while $T([\text{O}I])$ is lower than $T([\text{O}III])$ in the first case and slightly higher than $T([\text{O}II])$ in the second.

The $[\text{O}I]$ and $[\text{O}II]$ temperatures of the observed objects are shown in Fig. 8 together with the data of H$\text{II}$ galaxies, and galactic and extragalactic H$\text{II}$ regions from Pérez-Montero & Díaz (2003) and the photoionization models from Pérez-Montero & Díaz (2005) and the photoionization model of the first case and slightly higher than $T([\text{O}III])$ in the second. The $[\text{O}I]$ temperatures of the observed objects are shown in Fig. 8 together with the data of H$\text{II}$ galaxies, and galactic and extragalactic H$\text{II}$ regions from Stasińska (1980; solid line) and Stasińska (1990; dashed-dotted line) are also plotted. This figure shows the effect of the electron density on the derived $[\text{O}I]$ temperature which decreases with increasing density. The data points populate the region of the diagram spanned by model sequences but the observational errors are too large to allow an adequate test of the photoionization models themselves. The temperatures derived for two of the observed objects: SDSS J003218.60+150014.2 and SDSS J162410.11-002202.5 lie close to the theoretical relation for an electron density of $n_e = 10, 100$ and $500 \text{ cm}^{-3}$. The model sequences from Stasińska (1980; solid line) and Stasińska (1990; dashed-dotted line) are also plotted. This figure shows the effect of the electron density on the derived $[\text{O}I]$ temperature which decreases with increasing density. The data points populate the region of the diagram spanned by model sequences but the observational errors are too large to allow an adequate test of the photoionization models themselves. The temperatures derived for two of the observed objects: SDSS J003218.60+150014.2 and SDSS J162410.11-002202.5 lie close to the theoretical relation for an electron density of $n_e = 10 \text{ cm}^{-3}$, while for the other one: SDSS J002101.03+005248.1, they lie closer to sequences for electron densities larger than $100 \text{ cm}^{-3}$. This is consistent with the trend shown by the values of $n_e$ measured for the three objects.

For this last object, the value of $T([\text{O}II])$ derived from the measured $T([\text{O}II])$ according to the widely used fit to the photoionization models by Stasińska (1990), is larger than the measured one by $2200 \text{ K}$ which translates into a lower O$^+/\text{H}^+$ ionization ratio by a factor of 4 and a lower total oxygen abundance by 0.17 dex. It should be remarked that this is the procedure usually followed, even in the cases in which measured values of $T([\text{O}II])$ exist (see Izotov, Thuan & Lipovetsky 1994). Also, in doing so, no uncertainties are attached to the $T([\text{O}II])$ vs. $T([\text{O}II])$ relation with the final outcome of a reported $T([\text{O}II])$ which carries only the usually small observational error found in the derivation of $T([\text{O}II])$ and translates into very small errors in the oxygen ionic and total abundances. Thus it is possible, and even frequent, to find reported values of $T([\text{O}I])$ and $T([\text{O}II])$ with quoted fractional errors lower than 1% and absolute errors actually less than that quoted for $T([\text{O}II])$ (Izotov & Thuan 1998).

Recently, this procedure has been justified by Izotov & al. (2004) on the basis of an analysis of SDSS data. In this work it is argued that, despite a large scatter, the relation between $T([\text{O}II])$ and $T([\text{O}II])$ derived from observations follows generally the one obtained by models, and therefore they adopt $T([\text{O}II])$ as derived from their photoionization models. However, the large errors attached to the electron temperature determinations, in many cases around $\pm 2000 \text{ K}$ for $T([\text{O}II])$, actually precludes the test of such a statement. In fact, most of the data with the smallest error bars lie below and above the theoretical relation.

Regarding the $[\text{S}II]$ temperatures, our values fit well the relation between $T([\text{O}II])$ and $T([\text{S}II])$ found by Garnett (1992) as can be seen in Fig. 8. For the objects for which we have measured $T([\text{N}II])$, this is equal to $T([\text{S}II])$ within the errors.

The abundances derived for the observed objects show the characteristic low values found in strong line H$\text{II}$ galaxies (Terlevich et al. 1991, Hoyos & Díaz 2006): $12+\log(O/H) = 8.0$, within the errors, for SDSS J002101.03+005248.1 and SDSS J003218.60+150014.2 and slightly lower $12+\log(O/H) = 7.9$ for SDSS J162410.11-002202.5. The three objects have previous oxygen abundance determinations. They are part of the first edition of the SDSS H$\text{II}$ galaxies with oxygen abundance catalog, presented by Kniazev et al. (2004). These authors derived total oxygen abundances of $12+\log(O/H) = 8.18\pm0.04$ for SDSS J002101.03+005248.1, $12+\log(O/H) = 8.07\pm0.02$ for SDSS J003218.60+150014.2 and $12+\log(O/H) = 8.17\pm0.01$.
for SDSS J162410.11-002202.5, higher than ours by 0.17 dex, but consistent with the values we obtain from the analysis of the SDSS spectra for two of the objects: SDSS J002101.03+005248.1 (12+log(O/H) = 8.19±0.03) and SDSS J162410.11-002202.5 (12+log(O/H) = 8.14±0.02). For SDSS J003218.60+150014.2, our analysis of its SDSS spectrum yields a total oxygen abundance 12+log(O/H) = 7.93±0.03, lower than theirs by 0.14 dex and closer to the value derived by Ushkov et al. (2003) in their Hamburg/SAO Survey. The spectrum analyzed by Kniazev et al. (2004) was extracted from the first SDSS data release. This might point to a difference in the calibration routines of SDSS spectra from one release to the other.

The logarithmic N/O ratios found for the two galaxies for which there are T([OII]) and T([NII]) determinations are -1.06±0.10 and -1.26±0.12. For the third object we estimate a log(N/O) ratio of -1.11. They point to a constant value 0.14 dex, but consistent with the values we obtain from the analysis of the SDSS spectra for two of the objects: SDSS J002101.03+005248.1 which is lower by a factor of about 2.7. The analysis of the data according to the conventional lines described above would rise this S/O ratio somewhat, but still keeping it below the solar value.

On the other hand, the measurement of the [SII] IR lines allows the calculation of the sulphur abundance parameter $S_{23}$.

$$S_{23} = \frac{\text{[SII]} \lambda 6717, 31 + \text{[SIII]} \lambda 9069, 9532}{H\beta}$$

This parameter constitutes probably the best empirical abundance indicator for H\textsubscript{II} galaxies, since contrary to what happens for the widely used O\textsubscript{33} (R\textsubscript{23}) parameter (Pagel et al. 1979, Allain et al. 1979), the calibration is linear up to solar abundances, thus solving the degeneration problem usually presented by this kind of objects. This is particularly dramatic for objects with log O\textsubscript{33} ≥ 0.8 and 12+log(O/H) ≥ 8.0 which can show the same value of the abundance parameter while having oxygen abundances that differ by up to an order of magnitude. About 40% of the observed H\textsubscript{II} galaxies belong to this category (see Díaz & Pérez-Montero 1999). The logarithm of the $S_{23}$ parameter derived for our objects are given in the last row of table 10. Figure 11 shows the points corresponding to the objects in the log $S_{23}$ vs. 12+log(O/H) diagram, together with their observational error, and labeled as WHT objects.

The rest of the data correspond to H\textsubscript{II} galaxies from Pérez-Montero & Díaz (2005) together with the data of ten SDSS BCD galaxies presented by Kniazev et al. (2004) and analyzed by Pérez-Montero et al. (2004) (these objects are labeled as SDSS objects). The solid line shows the calibration by Pérez-Montero & Díaz (2005). Three objects are seen to clearly deviate from this line. Two of them correspond to two of the galaxies of Kniazev et al. (2004) for which no data on the [OII] 3727 line exist and therefore the O\textsuperscript{+}/H\textsuperscript{+} ratio is derived from the red [OII] 7325 lines. Both objects show low ionization parameters as estimated from the [SII]/[SIII] ratio and relatively high values of O/H as derived from the [NII]/H\alpha calibration (Díaz & Pérez-Montero 1999). The third object is Mrk709, an object that shows similar characteristics (see Pérez-Montero & Díaz 2003). These objects might be affected by shocks and deserve further study. Actually the accuracy of the $S_{23}$ calibration for H\textsubscript{II} galaxies, as a family, is only 0.10 dex (see Pérez-Montero & Díaz 2005). But obviously, more observations are needed in order to improve the $S_{23}$ calibration and truly understand the origin of the observed dispersion.

### 6.3 Ionization structure

The ionization structure of a nebula depends essentially on the shape of the ionizing continuum and the nebular geometry and can be traced by the ratio of successive stages of ionization of the different elements. With our data it is possible to use the O\textsuperscript{+}/O\textsuperscript{2+} and the S\textsuperscript{+}/S\textsuperscript{2+} to probe the nebular ionization structure. In fact, Vilchez & Pagel (1988) showed that the quotient of these two quantities that they called “softness parameter” and denoted by $\eta$ is intrinsically related to the shape of the ionizing continuum and depends on geometry only slightly. If the simplifying assumption of spherical geometry and constant filling factor is made, the geometrical effect can be represented by the ionization parameter which, in turn can be estimated from the [OII]/[OIII] ratio. Actually, the [OII]/[OIII] ratio depends on stellar effective temperature which, in turn, depends on metallicity, in the sense that for a given stellar mass, stars of higher metallicity have a lower effective temperature. Since
Figure 12. The relationship between log S\textsubscript{23} and metallicity, represented by 12+log(O/H), for the observed objects (solid circles), the HiI galaxies from Pérez-Montero & Díaz (2005) with data on the [S\textsc{iii}]\lambda 9069,9532 \AA emission lines (open circles), and SDSS BCDs galaxies (asterisks) from Pérez-Montero et al. 2006. The solid line shows the calibration made by Pérez-Montero & Díaz (2005).

The three observed objects have similar values of this quotient (between 0.2 and 0.3), and show oxygen abundances in a very narrow range, we can assume they also share a common value for their ionization parameter. Under these circumstances, the value of \eta points to the temperature of the ionizing radiation.

In panel (a) of Fig. 12, we show the relation between log(O\textsuperscript{+}/O\textsuperscript{2+}) and log(S\textsuperscript{+}/S\textsuperscript{2+}) for the observed objects (solid circles for values calculated using our methodology and solid diamonds for values derived using the conventional method) and the HiI galaxies from Pérez-Montero & Díaz (2005) for which the different oxygen and sulphur ionic ratios can be derived (open circles). In this diagram, diagonal lines correspond to constant values of \eta; the solid line corresponds to log \eta = 0.00. The region above this line corresponds to \eta > 1 and the region below the line corresponds to \eta < 1. The dashed lines correspond to log \eta = -0.35 and log \eta = 0.2. As can be seen in the figure, the HiI galaxies occupy the region of the diagram with -0.35 \leq log \eta \leq 0.20, which corresponds to high values of the ionizing temperature according to Vílchez & Pagel (1988). Two of the observed objects lie on the log \eta = -0.35 line. The third one, the one with the highest excitation, has log \eta = 0.15. An analysis along the conventional lines commented in the previous subsection, would yield the same value of \eta for the highest excitation object (although with different values of both O\textsuperscript{+}/O\textsuperscript{2+} and S\textsuperscript{+}/S\textsuperscript{2+} ratios) but widely different values of \eta for the other two objects: 0.19 and 0.30 indicating much lower ionization temperatures. This is inconsistent, however, with what is found if the same exercise is performed using the corresponding quotients of emission lines: log([O\textsc{ii}]/[O\textsc{ii}]), which does not require explicit knowledge of the line temperatures involved in the derivation of the ionic ratios, and therefore does not depend on the method to derive or estimate these temperatures. Panel (b) in Fig. 12 shows then the purely observational counterpart of panel (a). In this diagram diagonal lines represent constant values of log \eta’ defined by Vílchez & Pagel (1988) as:

\[
\log \eta' = \log \left[ \frac{[\text{O}\textsc{ii}]\lambda\lambda 3727, 29}{[\text{O}\textsc{ii}]\lambda\lambda 4959, 5007} \right] - \frac{0.14}{t_e} - 0.16
\]

where \(t_e\) is the electron temperature in units of 10\textsuperscript{4}. \eta and \eta’ are related through the electron temperature but very weakly, so that a change in temperature from 7000 to 14000 K implies a change in \log \eta by 0.1 dex, inside observational errors. Also, \log \eta’ is always less than \log \eta. In this diagram, the data for the three objects indicate values of \log \eta’ between -0.39 and -0.25, consistent with what is found by our analysis but inconsistent with the results obtained following the conventional methodology. Metallicity calibrations based on abundances derived according to this conventional method are probably bound to provide metallicities which are systematically too high and should therefore be revised.

6.4 The temperature fluctuation scheme.

At the end of the 60s and beginning of the 70s, Peimbert (1967), Peimbert & Coster (1967), and Peimbert (1971) established a complete analytical formulation to study the discrepancies between the abundances relative to hydrogen derived from recombination lines (RLs) and from collisionally excited lines (CELs) when a constant electron temperature is assumed. In the first of these works, Peimbert proposed that this discrepancy is due to spatial temperature variations which can be characterized by two parameters: the average temperature weighted by the square of the density over the volume considered, \(T_0\), and the root mean square temperature fluctuation, \(T^2\). They are given by

\[
T_0(X^{i+}) = \frac{\int T_e N_e (X^{i+}) dV}{\int N_e N(X^{i+}) dV}
\]  
(1)

and

\[
t^2(X^{i+}) = \frac{\int (T_e - T_0(X^{i+}))^2 N_e N(X^{i+}) dV}{T_0(X^{i+}) \int N_e N(X^{i+}) dV}
\]  
(2)

where \(N_e\) and \(N(X^{i+})\) are the local electron and ion densities of the observed emission lines, respectively; \(T_e\) is the local electron temperature; and \(V\) is the observed volume (Peimbert 1967).

It is possible to obtain the values of \(T_0\) and \(T^2\) using different methods. One possibility is to compare the electron temperatures obtained using two independent ways. Generally, temperatures originated in different zones of the nebula are used, one that represents the warmest regions and another representative of the coldest ones. In the absence of temperatures derived from recombination lines, the temperatures estimated from the hydrogen discontinuities, either from Balmer or Paschen series, representative of the temperature of the neutral gas, can be used.
Figure 13. Panel (a): Relation between log\((O^+/O^{2+})\) and log\((S^+/S^{2+})\) for the observed objects (solid circles for values calculated using our methodology and solid diamonds for values derived using the conventional method) and the H\(^{\text{II}}\) galaxies from P{\`e}rez-Montero & D{\`i}az (2005) for which the different oxygen and sulphur ionic ratios can be derived (open circles). Diagonals in this diagram correspond to constant values of \(\eta\). Panel (b): Relation between log\(([\text{OII}]/[\text{OIII}])\) and log\(([\text{SII}]/[\text{SIII}])\) for the observed objects (solid circles) and H\(^{\text{II}}\) galaxies from P{\`e}rez-Montero & D{\`i}az (2005) with data on the [S\(\text{II}\)] \(\lambda\lambda9069,9532\) \(\AA\) emission lines (open circles). Diagonals in this diagram correspond to constant values of \(\eta\).

We have followed Peimbert et al. (2003, 2002, 2004) and Ruiz et al. (2003) to derive the values of \(T_0\) and \(t^2\) for our WHT spectra by combining the Balmer temperature, \(T(Bac)\), and the temperature derived from the collisional [O\(\text{II}\)] lines, \(T([\text{OII}])\), therefore assuming a simple one-zone ionization scheme. Then, the relation for these two temperatures is given by:

\[
T([\text{OII}]) = T_0 \left[ 1 + \frac{1}{2} \left( \frac{91300}{T_0} - 3 \right) t^2 \right]
\]

and

\[
T(Bac) = T_0 \left( 1 - 1.67t^2 \right)
\]

The solution of this system of equations for each galaxy along with their corresponding errors are listed in table 11. The temperature fluctuations are almost negligible for two of our objects. They have \(t^2\)-values very similar to the ones derived by Luridiana et al. (2003) by combining observations from the literature and photoionization models for some BCDs and extragalactic H\(^{\text{II}}\) regions. Guseva et al. (2003) used the Balmer and Paschen jumps to determine the temperatures of the H\(^+\) zones of 22 low-metallicity H\(^{\text{II}}\) regions in 18 BCD galaxies, one extragalactic H\(^{\text{II}}\) region in M101 and 24 H\(^{\text{II}}\) emission-line galaxies selected from the DR3 of the SDSS. They found that these temperatures do not differ, in a statistical sense, from the temperatures of the [O\(\text{II}\)] zones, given \(t^2\)-values are close to zero. The greater \(t^2\)-value obtained for SDSS J003218.60+150014.2 is in the range of the values derived for giant extragalactic H\(^{\text{II}}\) regions (see Gonz{\`a}lez-Delgado et al. 1994; Peimbert et al. 2002; Jamet et al. 2003) or H\(^{\text{II}}\) regions in the Magellanic Clouds, such as 30 Doradus, LMC N11B and SMC N66 (Tsamis et al. 2004).

In the limit of low densities and small optical depths, and for \(t^2\) much lower than one, the electronic temperature for helium, \(T(\text{He}^+)\), is proportional to \(\langle \alpha \rangle\) and \(\beta\), the average value of the power of the temperature for the helium lines used to calculate the ionic abundances of He\(^+\), and the corresponding one for H\(^3\), respectively. Then, for \(\langle \alpha \rangle\) different from \(\beta\), this temperature is given by equation (14) of Peimbert (1967):

\[
T(\text{He}^+) = T(\text{He}^+\text{H}^{\text{II}}) = T_0 \left[ 1 + \left( \langle \alpha \rangle + \beta - 1 \right) \frac{t^2}{2} \right]
\]

The value of the power of the temperature for each helium line in the low density limit has been obtained from Benjamin et al. (1994). We have calculated \(\langle \alpha \rangle\) as the average value of \(\alpha\) weighted according to the observational errors. We have obtained values of \(\langle \alpha \rangle\) equal to -1.37, -1.42, and -1.43 for SDSS J002101.03+005248.1, SDSS J003218.60+150014.2, and SDSS J162410.11-002202.5, respectively. The value of \(\beta\) has been obtained from Storey & Hummer (1995) and is

| name                | \(T_0\)  | \(t^2\)   |
|---------------------|---------|-----------|
| SDSS J002101.03+005248.1 | 1.24±0.35 | 0.004±0.004 |
| SDSS J003218.60+150014.2 | 1.08±0.21 | 0.066±0.026 |
| SDSS J162410.11-002202.5 | 1.24±0.30 | 0.001±0.001 |

\(T_0\) in \(10^4\) K. Note that \(t^2\) is always greater than zero.
equal to -0.89. The results for T(Hβ) and their corresponding errors are listed in the last row of table 5.

The temperature for Hβ, T(Hβ), can be calculated from equation (20) in [Peimbert & Costero 1964] as:

$$T(H\beta) = T_0 \left[ 1 - 0.95t^2 \right]$$  \hspace{1cm} (6)

where we have taken $\beta = -0.89$ as above. The derived values for T(Hβ) and their errors are also given in table 5.

The line temperature for a collisionally excited line, CEL, for $t^2 \ll 1$, $(\Delta E_{CEL}/kT_0 - 1/2) \neq 0$, and $\alpha \neq 0$ is given by equation (20) of Peimbert & Costero (1964):

$$T_{CEL} = T_0 \left\{ 1 + \left[ \frac{(\Delta E_{CEL}/kT_0)^2 - 3\Delta E_{CEL}/kT_0 + 3/4}{\Delta E_{CEL}/kT_0 - 1/2} \right] \frac{t^2}{2} \right\}$$  \hspace{1cm} (7)

where $\Delta E_{CEL} = \Delta E_{mn}$ is the energy difference, in eV, between the upper (m) and lower (n) levels respectively of the atomic transition that produces the line.

For the case of $t^2 > 0$, and assuming a one-zone ionization scheme, we can derive the ionic abundances using the values calculated for $t^2$ equal to zero, and equation (15) of Peimbert et al. (2004):

$$\left[ \frac{N(X^{+})}{N(H^+)} \right]_{t^2>0} = \frac{T(H\beta)^{-0.89}}{T([OIII])^{0.5}} \frac{T(\alpha_{mn})}{T_{[OIII]}^{0.57}} \times \exp \left[ -\frac{\Delta E}{kT([OIII])} + \frac{\Delta E}{kT(\alpha_{mn})} \right] \times \left[ \frac{N(X^{+})}{N(H^+)} \right]_{t^2=0}$$  \hspace{1cm} (8)

where $T(\alpha_{mn})$ is given by equation (4). Using this expression, we have calculated the effect of the temperature fluctuations on the O2+/H+ abundance. In fact, given the high excitation of the object, this ionic abundance carries the highest weight in the total abundance of oxygen. The calculated value is 12+log(O2+/H+) = 8.09 ± 0.12 which yields a total oxygen abundance 12+log(O/H) = 8.12 ± 0.11. These values are higher than those given in Table III by 0.23 and 0.22 dex respectively.

7 CONCLUSIONS

We have performed a detailed analysis of newly obtained spectra of three Hii galaxies selected from the Sloan Digital Sky Survey Data Release 2, covering from 3200 to 10550 Å in wavelength. For the three objects we have measured four line temperatures: T([OIII]), T([SII]), T([OII]) and T([SII]) and the Balmer continuum temperature T(Bac). For two of the objects we have also measured T([NII]). These measurements and a careful and realistic treatment of the observational errors yield total oxygen abundances with accuracies between 5 and 9%. The fractional error is as low as 2% for the ionic O2+/H+ ratio due to the small errors associated with the measurement of the strong nebular lines of [OIII] and the derived T([OIII]), but increases to 15% for the O2+/H+ ratio. The accuracies are lower in the case of the abundances of sulphur (of the order of 20% for S+ and 12% for S2+) due to the presence of larger observational errors both in the measured line fluxes and the derived electron temperatures. The error increases further (up to 30%) for the total abundance of sulphur due to the uncertainties in the ICF.

This is in contrast with the small errors quoted for line temperatures other than T([OIII]) in the literature, in part due to the commonly assumed methodology of deriving them from the measured T([OIII]) through theoretical relations. These relations are found from photoionization models and no uncertainty is attached to them; therefore, the obtained line temperatures carries only the observational error found for the T([OIII]) measurement. If this methodology were to be adopted, the theoretical relations should be adequately tested and empirical relations between the relevant line temperatures should be obtained in order to quantify the corresponding model uncertainties.

We have compared our obtained spectra with those downloaded from the SDSS DR3 finding a satisfactory agreement. The analysis of these spectra yields values of line temperatures and elemental ionic and total abundances which are in general agreement with those derived from the WHT spectra, although for most quantities, they can only be taken as estimates since, due to the lack of direct measurements of the required lines, theoretical models had to be used whose uncertainties are impossible to quantify. Unfortunately, the spectral coverage of SDSS precludes the simultaneous observation of the [OIII]λλ 3727, 29 Å and [SII]λλ 9069, 9532 Å lines, and therefore the analysis can never be complete.

The ionization structure found for the observed objects from the O+2/O+3 and S+2/S+3 ratios points to high values of the ionizing radiation as traced by the values of the “softness parameter” $\eta$ which is less than one for the three objects. Line temperatures derived from T([OIII]) with the use of current photoionization models yield for the two highest excitation objects, much higher values of $\eta$ which would imply lower ionizing temperatures. This is however inconsistent with the ionization structure as probed by the measured emission line intensities.

Finally, we have measured the Balmer continuum temperature for the three observed objects and derived the temperature fluctuations as defined by Peimbert (1967). Only for one of the objects, the temperature fluctuation is significant and could lead to higher oxygen abundances by about 0.20 dex.

ACKNOWLEDGEMENTS

We are grateful to Jorge García-Rojas and César Esteban for calculating the effects of the temperature fluctuations over the derived ionic and total abundances. We are also grateful to an anonymous referee for his/her careful and constructive revision of the manuscript.

The WHT is operated in the island of La Palma by the Isaac Newton Group in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias. We thank the Spanish allocation committee (CAT) for awarding observing time.

Funding for the creation and distribution of the SDSS Archive has been provided by the Alfred P. Sloan Founda-
tion, the Participating Institutions, the National Aeronautics and Space Administration, the National Science Foundation, the US Department of Energy, the Japanese Monbukagakusho, and the Max Planck Society. The SDSS Web site is http://www.sdss.org

The SDSS is managed by the ARC for the Participating Institutions. The Participating Institutions are the University of Chicago, Fermilab, the Institute for Advanced Study, the Japan Participation Group, The Johns Hopkins University, the Korean Scientist Group, Los Alamos National Laboratory, the Max Planck Institute for Astronomy (MPIA), the Max Planck Institute for Astrophysics (MPA), New Mexico State University, the University of Pittsburgh, the University of Portsmouth, Princeton University, the United States Naval Observatory, and the University of Washington.

This research has made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France.

This work has been partially supported by DGICYT project AYA-2004-02860-C03 and the Spanish MEC FPU grant AP2003-1821. Elena Terlevich acknowledges support from the Spanish MEC through a grant for a sabbatical visit SAB-2004-0148. She and Roberto would like to thank the hospitality of the Astrophysics Group of the UAM during the completion of this work.
