ON THIN AIR READS: TOWARDS AN EVENT STRUCTURES MODEL OF RELAXED MEMORY

ALAN JEFFREY AND JAMES RIELY

Mozilla Research
DePaul University

Abstract. To model relaxed memory, we propose confusion-free event structures over an alphabet with a justification relation. Executions are modeled by justified configurations, where every read event has a justifying write event. Justification alone is too weak a criterion, since it allows cycles of the kind that result in so-called thin-air reads. Acyclic justification forbids such cycles, but also invalidates event reorderings that result from compiler optimizations and dynamic instruction scheduling. We propose the notion of well-justification, based on a game-like model, which strikes a middle ground.

We show that well-justified configurations satisfy the DRF theorem: in any data-race free program, all well-justified configurations are sequentially consistent. We also show that rely-guarantee reasoning is sound for well-justified configurations, but not for justified configurations. For example, well-justified configurations are type-safe.

Well-justification allows many, but not all reorderings performed by relaxed memory. In particular, it fails to validate the commutation of independent reads. We discuss variations that may address these shortcomings.

1. Introduction

The last few decades have seen several attempts to define a suitable semantics for shared-memory concurrency under relaxed assumptions; see Batty et al. [2015] for a recent summary. Event structures [Winskel 1986] provide a way to visualize all of the conflicting executions of a program as a single semantic object. In this paper, we exploit the visual nature of event structures to provide a fresh approach to relaxed memory models.

Consider a simple programming language where all values are booleans, registers (ranged over by \( r \)) are thread-local and variables (ranged over by \( x \) and \( y \)) are global. In order to define the semantics compositionally, variable read is defined as a choice among the possible

Key words and phrases: Relaxed Memory, Event Structures.

An earlier version of this paper appeared in LICS2016.
values that might be read. For example, the event structure for \((r=x; y=r;)\) is as follows.

\[
\text{init} \quad R_x 0 \quad W_y 0 \quad R_x 1 \quad W_y 1
\]

Register values are resolved via substitution and therefore do not appear in the event structure. The arrows represent program order, and the zigzag represents a primitive conflict. If two events are in conflict, then all following events are also in conflict.

This structure has two maximal conflict-free configurations, which represent a possible execution of the program:

\[
\text{init} \quad R_x 0 \quad W_y 0 \quad \text{and} \quad \text{init} \quad R_x 1 \quad W_y 1.
\]

If we suppose that this code fragment is embedded in a larger program, the two configurations are equally sensible: \(x\) could be anything. However, if we take init to be the top-level initialization of the program and suppose that variables are initialized to 0, then the first configuration above seems sensible, whereas the second does not: \(x\) must be 0.

A read event is justified by a matching visible write, drawn with a dashed arrow in the above configurations. Writes are hidden if they occur later or are blocked by an intervening write. When modeling executions of whole programs, one expects that all reads in a configuration must be justified.

In a happens-before model [Manson et al. 2005], all concurrent writes are visible, making this notion of justification quite permissive. Consider a program with two threads and the corresponding event structure, with events numbered for reference.

\[
(r_1=x; y=r_1;) \mid (r_2=y; x=r_2;)
\]  
\((P_1)\)

\[
\text{init} \quad R_x 0 \quad W_y 0 \quad R_x 1 \quad W_y 1 \quad R_y 0 \quad W_x 0 \quad R_y 1 \quad W_x 1
\]

Here, the events that are neither ordered nor in conflict are concurrent. The event structure for \(P_1\) has the following configuration, in which every read event is justified by a matching write that is either before it, or concurrent:

\[
\text{init} \quad R_x 0 \quad W_y 0 \quad R_y 0 \quad W_x 0
\]  
\((C_0)\)
Unfortunately, the event structure also has a configuration in which there is a cycle in justification-and-program-order:

\[ \text{init} \]
\[ R_x 1 \]
\[ W_y 1 \]
\[ R_y 1 \]
\[ W_x 1 \]

\((C_1)\)

Due to the cycle, any available value can be so justified, thus arising “out of thin air”. Some memory models have undefined semantics in the presence of such data races [Batty et al. 2011]. In the absence of such undefined behaviors, however, languages that claim memory safety must disallow thin-air values in order to preserve type safety.

Unfortunately, cycles such as those in configuration \(C_1\) cannot be banned outright without also banning useful program transformations, such as instruction reordering. For example, consider the following program.

\[(r_1=x; y=1;) || (r_2=y; x=1;) \quad (P_2)\]

The event structure for \(P_2\) is the same as that for \(P_1\) except that all writes have value 1. Thus, \(P_2\) also allows configuration \(C_1\). Clearly, if the order of the two instructions is swapped in either thread of \(P_2\), then it is possible for both threads to read 1. Since program transformations may not introduce new behaviors, \(C_1\) must also be considered a valid configuration of the original program.

There are several models in the literature designed to allow configuration \(C_1\) for \(P_2\), yet deny it for \(P_1\). Roughly these can be divided into two approaches: working with multiple executions [Manson et al. 2005; Jagadeesan et al. 2010] or working with axioms and rewrite rules [Cenciarelli et al. 2007; Saraswat et al. 2007; Pichon-Pharabod and Sewell 2016].

We propose a new approach, based on two-player games. The game is as follows: we start in configuration \(C\), and the player’s goal is to extend it to configuration \(D\). The opponent picks a configuration \(C'\) which includes \(C\), and whose new events are acyclically justified. The player then picks a configuration \(C''\) which includes \(C'\), and whose new events are also acyclically justified. If \(C''\) justifies \(D\) then the player has won, otherwise the opponent has won. If the player has a winning strategy for this game, we say that \(C\) \textit{Always Eventually (AE) justifies} \(D\).

From this game, we can define the \textit{well-justified} configurations inductively: \(\emptyset\) is well-justified; if \(C\) is well-justified and \(C\) AE-justifies \(D\) then \(D\) is well-justified.

Consider the following program, \(P_3\).

\[ r_1=x; y=1; \ || \ r_2=y; x=r_2; \quad (P_3) \]

We show that both reads may be resolved to 1 in the well-justified configuration \(\{30, 32, 34, 36, 38\}\). In this case the cyclic justifier models a valid execution, caused by a compiler or hardware optimization reordering \((r_1=x; y=1;)\) as \((y=1; r_1=x;)\).
We first show that $\emptyset$ AE-justifies $\{30, 34, 38\}$. The opponent may choose any configuration acyclically justified from $\emptyset$; the interesting choices are the maximal configurations $\{30, 31, 33, 35, 37\}$ and $\{30, 31, 34, 35, 38\}$. Since both of these include 35, which justifies 34, the player does not have to add any events to justify $\{30, 34, 38\}$. Note that $\emptyset$ does not AE-justify $\{30, 32\}$, since the opponent can choose the configuration $\{30, 31, 35, 33, 37\}$.

We now show that the configuration $\{30, 34, 38\}$ AE-justifies $\{30, 32, 34, 36, 38\}$. The opponent may choose any configuration acyclically justified from $\{30, 34, 38\}$; since any choice includes 38, which justifies 32, the player does not have to add any events to justify $\{30, 32, 34, 36, 38\}$. We have thus shown a cyclic configuration similar to $C_1$ is well-justified for $P_3$.

This reasoning fails for configuration $C_1$ of $P_1$. In this case, the player is unable to establish that $\emptyset$ AE-justifies $\{10, 14, 18\}$. We provide a proof in §5. Intuitively, the only maximal configuration available to the opponent is $\{10, 11, 13, 15, 17\}$, and this fails to justify 14 since there is no write of 1 to $y$.

We review the literature on confusion-free event structures in §2. In §3 we define well-justification and provide further examples. We give the definition for a Java-like happens-before model [Manson et al. 2005]. We discuss synchronization actions, such as locks, in §6.

Perhaps the most important property of a relaxed memory model is DRF: that programs without data races behave as they would with strong memory—that is, as they would with sequentially consistent memory [Lamport 1979]. In §4, we describe our proof of the DRF theorem, which we have verified in Agda.

In §5, we show that invariant reasoning is possible using our definition. We state a general theorem—also verified in Agda—which is sufficient to establish type safety for static allocation.

We describe some of the limitations of our definition in §7. While the definition presented here is a step in the right direction, it fails to validate common reorderings, such as the reordering of reads on different variables. We give an alternative definition that is better behaved on the Java Memory Model causality test cases [Pugh 2004]. The induction principle used in our proof of DRF fails for this alternative definition.

The paper ends with a discussion of related work and open problems.

The Agda development for this paper is available https://perma.cc/WAC3-JLXV.

2. Event Structures

Event structures were introduced by Winskel [1988] as a non-interleaving model of concurrency. They are notable for providing a compact model of concurrent systems, for example an event structure model for $n$ concurrent processes will often have only $O(n)$ events, compared to the $O(2^n)$ states in a labeled transition system.
In this section, we review the definitions associated with conflict-free labeled event structures, and their visualization as graphs. Readers familiar with event structures can skip to §3, where the new material begins.

A partial order \((E, \leq)\) is a set \(E\) (the event set) equipped with a reflexive, transitive, antisymmetric relation \(\leq\) (the causal order). A well order is a partial order that has no infinite decreasing sequence.

We visualize partial orders as directed acyclic graphs where edges denote order. For example the order on \(\{0, 1, 2, 3\}\) where \(0 \leq 1 \leq 2\) and \(0 \leq 3\) is visualized on the right.

A prime event structure \((E, \leq, \#)\) is a well order together with a symmetric relation \(\#\) on \(E\) (the conflict relation), such that if \(c \# d \leq e\) then \(c \# e\).

For any prime event structure, define the primitive conflict relation \(\#_\mu\) on \(E\) as \(d \#_\mu e\) whenever \(d \# e\) and for any \(d \geq b \# c \leq e\) we have \(d = b\) and \(c = e\). Primitive conflict is also known as minimal conflict. A prime event structure is confusion-free [Nielsen et al. 1979] whenever \(\#_\mu\) is transitive, and if \(c \leq d \#_\mu e\) then \(c \leq e\).

For any confusion-free event structure, define the primitive conflict equivalence \(d \sim e\) whenever \(d = e\) or \(d \#_\mu e\). It is routine to show that primitive conflict equivalence is symmetric and transitive, and hence forms an equivalence on \(E\).

We visualize confusion-free event structures by including the primitive conflict equivalence in the visualization. For example the event structure which extends the previous partial order with \(1 \# 3\) and \(2 \# 3\) has \(1 \sim 3\), so is visualized as on the right.

A labeled event structure \((E, \leq, \#, \lambda)\) over a label set \(\Sigma\) is a prime event structure together with a function \(\lambda : E \rightarrow \Sigma\).

We visualize labeled event structures as node-labeled graphs. For example the labeled event structure which extends the previous event structure with labeling \(\lambda(0) = \text{init}\), \(\lambda(1) = (\text{Rx} 0)\), \(\lambda(2) = (\text{Wy} 1)\) and \(\lambda(3) = (\text{Rx} 1)\) is visualized as follows.

For any prime event structure, a set \(C \subseteq E\) is conflict-free whenever there is no \(d, e \in C\) such that \(d \# e\). \(C\) is down-closed whenever \(d \leq e \in C\) implies \(d \in C\). A configuration is a set which is conflict-free and down-closed.

Since configurations are conflict-free, they can be visualized as node-labeled directed acyclic graphs, for example the two largest configurations for the previous labeled event structure are

\[
\begin{array}{c}
\text{init} \\
\text{Rx} 0 \\
\text{Wx} 1 \\
\text{Rx} 1
\end{array}
\]

and

\[
\begin{array}{c}
\text{init} \\
\text{Rx} 0 \\
\text{Wx} 1 \\
\text{Rx} 1
\end{array}
\]

Given labeled event structures \(ES_1 = (E_1, \leq_1, \#, \lambda_1)\) and \(ES_2 = (E_2, \leq_2, \#, \lambda_2)\) (without loss of generality, we assume event sets \(ES_1\) and \(ES_2\) are disjoint) define the parallel composite event structure \(ES_1 \parallel ES_2\) as having:

- event set \(E\) is \(E_1 \cup E_2\),
- causal order \(\leq\) is \(\leq_1 \cup \leq_2\).
• conflict \# is \#_1 \cup \#_2, and
• labeling \( \lambda \) is \( \lambda_1 \cup \lambda_2 \).

The sum event structure \( ES_1 + ES_2 \) is the same except:
• conflict \# is \#_1 \cup \#_2 \cup (E_1 \times E_2) \cup (E_2 \times E_1).

We write \( 0 \) for the empty event structure with event set \( \emptyset \).

For a label \( \sigma \in \Sigma \), the prefix \( \sigma \bullet ES_0 \) introduces a new \( \sigma \)-labeled event ordered before all the events of \( ES_0 \). It is defined as having:
• event set \( E \) is \( E_0 \cup \{ \bot \} \),
• causal order \( \leq \) is \( \leq_0 \cup (\{ \bot \} \times E) \),
• conflict \# is \#_0, and
• labeling \( \lambda \) is \( \lambda_0 \cup \{ (\bot, \sigma) \} \).

Using an appropriate alphabet (discussed in more detail in §3), we can give the semantics of a simple shared-memory concurrent language. The construction uses sum, parallel composition, prefix and the empty event structure.

Let \( r \) range over registers. A store maps registers to values. Let \( \rho \) range over stores and \( \rho_0 \) be the initial store, which maps all registers to 0. We write \( \rho[r \mapsto v] \) for store update:
\[
\rho[r \mapsto v](r') = \begin{cases} 
v & \text{if } r = r' \\
\rho(r') & \text{otherwise} \end{cases}
\]

Let \( M \) range over expressions, which may include registers, but not variables. Let \( V \) be a set of values. Let \( \mathcal{M}[\cdot] \) be an interpretation that maps expressions and stores to values.

We give the semantics of a single-threaded program, featuring reads, writes and conditionals as an event structure:
\[
\begin{align*}
\mathcal{T}[r = x; T]\rho & \triangleq \sum_{v \in V}(R x v) \bullet \mathcal{T}[T](\rho[r \mapsto v]) \\
\mathcal{T}[x = M; T]\rho & \triangleq (W x \mathcal{M}[M]\rho) \bullet \mathcal{T}[T]\rho \\
\mathcal{T}[\text{done}]\rho & \triangleq 0 \\
\mathcal{T}[\text{if } M T_1 \text{ else } T_0]\rho & \triangleq \begin{cases} 
\mathcal{T}[T_0]\rho & \text{if } \mathcal{M}[M]\rho = 0 \\
\mathcal{T}[T_1]\rho & \text{otherwise} \end{cases}
\end{align*}
\]

A program is an collection of threads \( T_1 \parallel \cdots \parallel T_n \), interpreted as parallel composition of event structures with an initial event:
\[
\mathcal{P}[T_1 \parallel \cdots \parallel T_n] \triangleq \text{init} \bullet (\mathcal{T}[T_1]\rho_0 \parallel \cdots \parallel \mathcal{T}[T_n]\rho_0)
\]

We use standard abbreviations. For example, the program
\[
\text{if } (x==0) \{ y=1; \}
\]
desugars to the following.
\[
r=x; \text{if}(r==0)\{y=1; \text{done}\} \text{ else } \{ \text{done} \}
\]

If we take \( V = \{0, 1\} \), then this has semantics
\[
\text{init} \bullet (((R x 0) \bullet (W y 1) \bullet 0) + ((R x 1) \bullet 0))
\]

6
visualized as follows.

Note that in this semantics, conflict is only introduced by reads. Each conflicting event represents the read of a distinct value; since only one value can be read, the events are in primitive conflict.

3. MEMORY EVENT STRUCTURES

A memory alphabet \((\Sigma, R, W, J, K)\) consists of

- a set \(\Sigma\) (the actions),
- set \(R \subseteq \Sigma\) (the read actions),
- set \(W \subseteq \Sigma\) (the write actions),
- binary relation \(J \subseteq (W \times R)\) (justification), and
- binary relation \(K \subseteq J\) (synchronized justification).

When \((a, b) \in J\), we say that a justifies \(b\). Synchronization does not play a role in this section; we return to it in §6.

A memory event structure over such a memory alphabet is a confusion-free labeled event structure over \(\Sigma\).

The prototypical memory alphabet consists of an initial action, and read and write actions over some set of variables \(X\), and some set of values \(V\):

\[
\Sigma = R \cup W \\
R = \{(Rxv) | x \in X, v \in V\} \\
W = \{(Wxv) | x \in X, v \in V\} \cup \{\text{init}\}
\]

In §2 we saw that such an alphabet can be used to give the semantics for a simple shared-memory concurrent language. The justification relation for this alphabet is that \(\text{init}\) justifies a read of 0, and that a write of \(v\) justifies a read of \(v\) to the same variable:

\[
J = \{\text{init}, (Rx0) | x \in X\} \\
\cup \{(Wxv), (Rxv) | x \in X, v \in V\}
\]

In a memory event structure, an event \(e\) is a read event whenever \(\lambda(e) \in R\), and a write event whenever \(\lambda(e) \in W\). The sets \(R\) and \(W\) need not be disjoint; thus, a memory alphabet may include read-modify-write actions such as exchange, compare-and-set or increment. The semantics of these operators as event structures is straightforward, following the style given in §2.

In a memory event structure, we can lift justification from labels to events, but this is not just a matter of looking at the labeling, since events should not be justified by later events, by events in conflict, or by events with an intervening event in read-write conflict. For example, in the program

\[
\text{if}(y)\{x=0;\}\text{ else }\{x=1; x=x;\}
\]
has the following event structure semantics, where we visualize justification as a dashed edge.

There is no event labeled $(W_y 1)$; therefore, the only justified read of $y$ is 0, not 1. Neither event labeled $(W_x 0)$ justifies $(R_x 0)$: one is in conflict with it and the other is later. Finally, init does not justify $(R_x 0)$ because $(W_x 1)$ is an intervening event in read-write conflict. Thus, the only justified read of $x$ is 1, not 0.

In a memory event structure, we say write event $d$ justifies read event $e$ whenever:

1. $(\lambda(d), \lambda(e)) \in J$,
2. we do not have $e < d$,
3. we do not have $d \# e$, and
4. there is no $d < b < c \sim e$ such that $(\lambda(b), \lambda(c)) \in J$.

Visually these conditions are that $d$ cannot justify $e$ when:

Item (4) provides a formal definition of what it means for $b$ to be in read-write conflict with $e$. The following statement is equivalent: “there is no $d < b < e \sim c$ such that $b$ justifies $c$.” However, we cannot use this as the definition without worrying about circularity.

**Definition 3.1** (Justified). A configuration $C$ is justified whenever every read event in $C$ is justified by at least one write event in $C$.

For example, the program $y=x; \quad$ has two maximal configurations, but only one of them is justified:

An event may have multiple justifiers in a single configuration. In drawings, we choose one. For example, the program $(x=0; \mid x=x;) \quad$ has only one maximal configuration. The read event in this configuration has two justifiers:
Unfortunately, justified configurations, although necessary, are not a sufficient condition for modeling valid executions, as they allow cycles in the union of causal order and justification, which cause thin air reads. For example, the program $P_1$ from the introduction includes the justified configurations \{10, 11, 13, 15, 17\} and \{10, 12, 14, 16, 18\}:

$$(r1=x; y=r1;) \parallel (r2=y; x=r2;)
$$

$\text{init}^{10} \xrightarrow{10} R_x 0 \xrightarrow{11} R_y 0 \xrightarrow{13} R_x 1 \xrightarrow{12} R_y 1 \xrightarrow{14} W_y 0 \xrightarrow{15} W_x 0 \xrightarrow{17} W_y 1 \xrightarrow{16} W_x 1 \xrightarrow{18} \text{init}^{10}$$

In the latter, there is a cycle in causal+justification order. It is straightforward to ban such cycles.

Recall that a configuration is a subset of the event set $E$.

**Definition 3.2 (Acyclically justified).** On configurations, define $C$ justifies $D$ whenever for any read event $d \in D \setminus C$ there exists a write event $c \in C$ such that $c$ justifies $d$.

- Write $C \preceq D$ whenever $C \subseteq D$ and $C$ justifies $D$.
- Write $\preceq^*$ for the reflexive, transitive closure of $\preceq$.
- Define $C$ is acyclically justified whenever $\emptyset \preceq^* C$.

A justified configuration is acyclically justified whenever the order induced by causal order and justification is acyclic. Any acyclically justified configuration is also justified.

For example, for $P_1$, we have that $\emptyset \preceq \{10\}$, since 10 is not a read. In addition, we have $\{10\} \preceq \{10, 11\}$ and $\{10\} \preceq \{10, 13\}$ since 10 justifies both 11 and 13. Taking a maximal configuration at each step, we have:

$\emptyset \preceq \{10\} \preceq \{10, 11, 13, 15, 17\}$

However, there is no such chain leading from $\emptyset$ to $\{10, 12, 14, 16, 18\}$.

Consider the following program.

$y=x; \parallel x=1 \parallel r=y$; \hspace{1cm} (P_4)

$\text{init}^{40} \xrightarrow{40} R_x 0 \xrightarrow{41} R_y 0 \xrightarrow{45} W_y 0 \xrightarrow{46} W_x 0 \xrightarrow{44} \text{init}^{40} \xrightarrow{40} R_x 1 \xrightarrow{42} R_y 0 \xrightarrow{46} W_y 1 \xrightarrow{47} W_x 1 \xrightarrow{44} R_y 1$.

In this case the write to $x$ is immediately available, since it is not causally dependent on any read. Thus:

$\emptyset \preceq \{40, 47\} \preceq \{40, 47, 41, 45\} \preceq \{40, 47, 41, 45, 43\}$

$\emptyset \preceq \{40, 47\} \preceq \{40, 47, 42, 46\} \preceq \{40, 47, 42, 46, 44\}$

Here the read of $x$ is a coin-toss, which determines whether it is possible to read ($R_y 1$): A configuration that contains 41 cannot also contain 44.

The second of these sequences can be seen in Figure 1, read from top to bottom. The events included in each successive configuration are highlighted using a darker, blue background. Events that are in conflict with an included event are covered in white. Thus in
a maximal configuration, such as the last configuration in Figure 1, all events are either highlighted or covered.

Acyclic justification rules out cycles, since in any acyclically justified $C$, there must be configurations $\emptyset = C_0 \lessdot \cdots \lessdot C_n = C$, and for any read event $e \in C$ there must be a $j$ such that $e \in C_{j+1}$ and a $d \in C_j$ which justifies $e$. Since configurations are $\leq$-closed, this means that there is no infinite sequence $d_1 \leq e_1, d_2 \leq e_2, \ldots$, where $d_i$ justifies $e_{i+1}$, and in particular there are no cycles.

Unfortunately, acyclic justification is too strong a requirement, as it rules out some valid executions in the presence of optimizations which reorder memory accesses. For example, the program $P_3 = (r=x; y=1; || x=y;)$. In this case the cyclic justifier models a valid execution, caused by a compiler or hardware optimization reordering $\langle r=x; y=1; \rangle$ as $\langle y=1; r=x; \rangle$. If we are going to admit such reorderings, we cannot model valid executions by a property of configurations, and must look at the entire event structure (this observation was made, in a different model, by Batty et al. [2015]).

**Definition 3.3 (Well-justified).** On configurations, define $C$ always eventually justifies (AE-justifies) $D$ whenever for any $C \lessdot^* C'$ there exists a $C' \lessdot^* C''$ such that $C''$ justifies $D$. Write $C \sqsubseteq D$ whenever $C \subseteq D$ and $C$ AE-justifies $D$.

Write $\sqsubseteq^*$ for the reflexive, transitive closure of $\sqsubseteq$.

Define $C$ is well-justified whenever $C$ is justified and $\emptyset \sqsubseteq^* C$.

Note the player’s choice of $D$ is not required to include the opponents choices in $C'$.

The definition requires only that the player can find an extension $C''$ of $C'$ that justifies every event in $D$.
A well-justified configuration must be both justified and AE-justified. The notion of AE-justification describes when a read event is justified by some write event no matter which execution path is chosen. AE-justification has the flavor of a two-player game: in a configuration $C_i$, the opponent chooses a $C'_i \preceq C''_i$; after which the player chooses a $C''_i \preceq C''_i$ which justifies $C_i+1$. If the player can justify $C_i+1$ regardless of the opponent move, then the player wins the round. The player well-justifies $C$ if they can repeat this game to move from the initial configuration $\emptyset$ to the final configuration $C$.

Any acyclically justified configuration is AE-justified.

**Example 3.4.** Consider the proof of acyclic justification given in Figure 1. Starting from $C_0 = \emptyset$, the player follows the proof of acyclic justification to select $C_1 = \{40, 47\}$, then $C_2 = \{40, 47, 42, 46\}$ and finally $C_3 = \{40, 47, 42, 46, 44\}$. In each case, the events in $C_i$ are justified by an extension $C''_{i-1}$ of $C_{i-1}$, regardless of the opponent’s choice of $C'_{i-1}$. For example, the opponent may choose $C_1 = \{40, 47, 41\}$. Even though 41 and 42 are in conflict, the player may choose $C_2 = \{40, 47, 42, 46\}$; the read (R x 1) of 42 is justified by 42, which the opponent cannot remove.

For any opponent move $\emptyset \preceq \emptyset$, the player must choose $C_0 \preceq \emptyset$ so that $C''_0$ justifies $C_1$. In this case, the player can always choose $C''_0 \supseteq \{40, 47\}$, since 40 and 47 conflict with no event and do not require justification. The first two moves of the player can be collapsed, choosing $C_1$ to be $\{40, 47, 42, 46\}$, since 42 can be justified regardless of the opponent move. However, the last two moves cannot be collapsed. The player cannot initially select 44; in this case the opponent would win by choosing $C'_0 = \{40, 41, 43, 45\}$. \hfill \square
Example 3.5. We now consider the proof that \( P_3 \) is well-justified to read all ones, given in Figure 2. The previous strategy does not work, since the goal configuration is not acyclically justified.

The player chooses \( C_1 = \{30\} \), \( C_2 = \{30, 34, 38\} \) and finally \( C_3 = \{30, 34, 38, 32, 36\} \). As in the previous example, the first two player moves can be collapsed, but not the last two. We show the first two player moves separately to make the opponent choices clear. The opponent can choose \( C'_1 \) to include any events except \( 32 \)(and therefore \( 36 \)); there is no acyclically justified configuration that includes \( 32 \). For this reason events \( 32 \) and \( 36 \) are gray in the top configuration of Figure 2. The opponent option to include \( 33 \) prevents the player from selecting \( 32 \). The \((Rx1)\) cannot be justified in this case. However, \((Ry1)\) can be justified regardless of the opponent’s choice. Thus \( 34 \) can be included in \( C_1 \) (or \( C_2 \), as shown).

Once the player has won the round including \( 34 \), the opponent is no longer at liberty to include \( 33 \)—the choice has been made. Thus the player may include \( 32 \) in the next round.

This reasoning holds even if the write to \( y \) is conditional, as in the following variation:

\[
\begin{align*}
r_1 &= x; \text{ if}(r_1 < 2) \{y=1;\} \mid r_2 &= y; x=r_2;
\end{align*}
\]

As before, there is no acyclically justified configuration of the event structure that reads a value other than 0 for \( x \). Thus the player can choose an initially choose a configuration containing \((Ry1)\), and play proceeds as before.

Example 3.6. As noted in the introduction, configuration \( C_1 \) of \( P_1 \) fails to be well-justified.

We provide a proof in §5. Intuitively, the player is unable to select \( 14 \in C_1 \), because the opponent can choose \( 11 \in C'_0 \).

In the process of revising the Java Memory Model, Pugh [2004] developed a set of twenty causality test cases. Using hand calculation, we tested our semantics against nineteen of these cases. (TC9 is based on the idea that an execution should be allowed if there exists an augmentation, such as thread inlining, that allows it. This is a non-goal for our semantics; therefore, we do not consider TC9.)

Our semantics agrees with sixteen of the test cases and disagrees with three: TC3, TC7 and TC11. In §7, we discuss TC7, which best elucidates the issues.

Also by hand calculation, we found that our semantics gives the desired results for all examples in Batty et al. [2015, §4] and all but one in Ševčík [2008, §5.3]: redundant-write-after-read-elimination—this counterexample applies to any sensible non-coherent semantics.

Example 3.7. We consider the redundant-read-elimination counterexample of [Ševčík 2008, §5.3.2], given in Figure 3. TC18 of [Pugh 2004] is similar. The question is whether there is a well-justified configuration that includes event \( e \).

Starting from the empty set, the maximal acyclically justified configurations are \( \{a, b, f, d, h\} \) and \( \{a, c, g, d, h\} \), both of which include \( h \) with label \((Wx1)\). Therefore the player can choose \( \{a, c, g\} \).

Having secured \( g \) with label \((Wy1)\), the player can subsequently add \( e \), with label \((Ry1)\).

At this point, the player has two possible extensions, depending on the choice between \( i \) and
\texttt{y=x;  \textbar \textbar  if(y){x=y;} else {x=1;}}

\textbf{Figure 3.} AE-order for Ševčík §5.3.2

\(j\). Both choices are \textit{AE-justified}, but only the choice of \(j\) can be extended to a \textit{justified} configuration, which is therefore \textit{well-justified}: The AE-justified configuration \{\(a, c, e, g, i\}\} cannot be extended to include an event labeled \((Wx\ 1)\), which is necessary to justify \(e\) with label \((Rx\ 1)\).
This example shows the importance of limiting the power of the opponent at each step. If we were to allow the opponent to choose configurations using AE-justification, rather than acyclic justification, then the opponent could choose \( \{a, c, e, g, i\} \) to extend the empty set, disabling the players initial choice of \( \{a, c, g\} \). In this case, one can prevent the attack by limiting the opponent to well-justification rather than AE-justification. By adding another variable, however, one can construct an example in which well-justification gives the opponent additional power over acyclic justification.

4. **Data-race-free event structures**

We say that \( ES' \) is an augmentation of \( ES \) if it has same events, conflict and labels, and possibly more order. Formally, \( (E, \leq', \#, \lambda) \) is an augmentation of \( (E, \leq, \#, \lambda) \) if \( \leq \subseteq \leq' \).

It is straightforward to show that justification, acyclic justification and well-justification are all reflected by augmentation. For example, if \( ES' \) augments \( ES \) and \( C \) is a well-justified configuration of \( ES' \) then \( C \) is a well-justified configuration of \( ES \).

A **sequential** memory event structure is one where, for any events \( d \) and \( e \), either \( d \leq e \), \( e \leq d \) or \( d \# e \). A **sequentially consistent** configuration of a memory event structure is a justified configuration of a sequential augmentation of it. That is, a configuration \( C \) of \( ES \) is sequentially consistent if there exists an augmentation \( ES' \) of \( ES \) such that \( ES' \) is sequential and \( C \) is a justified configuration of \( ES' \).

Note that in a sequential memory event structure, if \( d \) justifies \( e \) then \( d \leq e \). It follows that any justified configuration of a sequential memory event structure is well-justified, and hence that any sequentially consistent configuration of a memory event structure is well-justified.

The converse is not true. There are well-justified configurations that are not sequentially consistent, due to data races. For example, the program \( (w=1; || y=(w<=x); || z=(x<=w); || x=1;) \) has semantics with configuration:

This is acyclically justified, and hence well-justified, but not sequentially consistent. In this section, we shall show that such data races are the only source of configurations which are well-justified but not sequentially consistent.

In a memory event structure, define concurrent events \( d \) and \( e \) to be a **read-write race** whenever there is some \( c \sim e \) such that \( d \) justifies \( c \), as shown on the left below. Define concurrent events \( d \) and \( e \) to be a **write-write race** whenever there is some \( b \sim c \) such that \( d \) justifies \( b \) and \( e \) justifies \( c \), as shown on the right below.
Define a configuration to be *data-race-free* when it contains no read-write or write-write races. Recall that \( \sim \) is reflexive; thus, we may also have \( c = e \) in the left diagram and \( b = c \) in the right.

We state the theorem generally for any memory event structure that is read-enabled and commutative. The prototypical example, given in §3, satisfies both these criteria.

A memory event structure is *read-enabled* whenever, for any read event \( e \) there exists some \( c \leq e \sim d \) such that \( c \) justifies \( d \), as shown on the right. Any event structure that is the semantics of a program is read enabled. Read enabledness ensures that every read operation in a program can be satisfied by some preceding write. This is true because of the init event which justifies reading 0 on every variable and, therefore, is in read-write conflict with every read. For example, if \( e \) is \((R x 1)\), then it suffices to take \( c \) to be init, since init justifies \((R x 0)\), which is in primitive conflict with \((R x 1)\).

A memory event structure is *commutative* whenever \( c \sim d \) and \( d \) justifies \( e \) implies there exists \( b \sim e \) where \( c \) justifies \( b \), that is:

\[
\begin{align*}
\text{c} & \sim \text{d} \\
\text{e} & \sim \text{b} \sim \text{e} \\
\text{implies} & \\
\text{c} & \sim \text{d} \sim \text{e}
\end{align*}
\]

If read and write actions are disjoint, then it follows immediately that any event structure that is the semantics of a program will be commutative, since read is defined as a sum over all possible values. Commutativity ensures that all writes can be read from.

Read-modify-write operators such as swap and fetch-and-add are commutative, since these always write. Compare-and-set (CAS) is commutative if we interpret a failed CAS as both read and write (of the old value), but not if we consider a failed CAS only as a read. For example, if failed CAS is considered a read, then \((\text{CAS} x 01)\) generates the following event structure for bit register \( x \), where \((\text{RMW} x 01)\) denotes a successful CAS and \((R x 1)\) denotes a failed CAS.

\[
\begin{align*}
\text{init} & \sim \text{RMW} x 01 \\
\text{R x 1} & \sim \text{R x 1}
\end{align*}
\]

The \((\text{RMW} x 01)\) event may justify some other read of \( x \); however, the minimal conflicting event \((R x 1)\) is a plain read, which justifies nothing. We leave weakening commutativity as future work.

**Theorem 4.1 (DRF).** In any commutative read-enabled memory event structure, if all sequentially consistent configurations are data-race-free, then all well-justified configurations are sequentially consistent.

**Proof.** Define a configuration \( C \) to be *pre-justified* if every read action \( e \in C \) is justified by a write action \( d \in C \) where \( d \leq e \). It is routine to show that any pre-justified configuration is sequentially consistent. The core lemma of the proof follows [Lochbihler 2013], which is that if \( C \) is pre-justified, and \( C \) justifies \( D \), then \( D \) is pre-justified. After this, the proof is routine: we first show that if \( C \) is pre-justified and \( C \preceq^* D \) then \( D \) is pre-justified; then that if \( C \) is pre-justified and \( C \preceq^* D \) then \( D \) is pre-justified. The result follows, since \( \emptyset \) is trivially pre-justified. This proof has been mechanized in Agda. \( \square \)
5. INVARiANTS

While there is no formal definition of “thin-air read” [Batty et al. 2015], the examples point to a failure of inductive reasoning, typically due to a cycle in the union of the causal and data dependency orders. In order to establish that these forms of thin-air read are impossible, it is sufficient to show that is possible to reason inductively. In this section, we show that well-justification enables inductive reasoning.

We consider a limited form of invariant reasoning, which is strong enough to capture non-temporal safety properties, such as type safety. Given a suitable notion of formula, \( \phi \), we show that if, in every configuration of \( ES \), the \textit{read} events satisfy \( \phi \), then, in every configuration of \( ES \), all events satisfy \( \phi \). Significantly, the result can be applied without reasoning about well-justification.

To keep the setting as simple as possible, we consider logics over labels rather than events. In order to establish the result, we must restrict attention to logics that are subset closed. This allows the expression of certain safety properties such as \( x \neq 1 \), but not liveness properties such as \( x = 1 \).

For a label set \( \Sigma \), a program logic \((\Phi, \models)\) consists of:

- a set \( \Phi \) (the \textit{formulae}), and
- a binary relation \( \models \) between \( \mathcal{P}(\Sigma) \) and \( \Phi \) (satisfaction).

A formula \( \phi \) is subset closed whenever \( A \subseteq B \models \phi \) implies \( A \models \phi \). It is satisfiable whenever \( A \models \phi \) for some \( A \). It respects justification whenever \( A \) justifies \( B \) and \( A \models \phi \) implies \( B \models \phi \).

For any configuration \( C \), let \( \Sigma(C) \) be the labels of \( C \):

\[
\Sigma(C) = \{ \lambda(e) \mid e \in C \}
\]

A formula \( \phi \) is an invariant of a memory event structure whenever \( \Sigma(C) \cap R \models \phi \) implies \( \Sigma(C) \models \phi \) for any configuration \( C \) (recalling that \( R \) is the set of all read actions).

A formula \( \phi \) is a tautology of a memory event structure whenever \( \Sigma(C) \models \phi \) for any well-justified configuration \( C \).

**Theorem 5.1.** For any satisfiable, subset-closed \( \phi \) which respects justification, if \( \phi \) is an invariant of \( ES \) then \( \phi \) is a tautology of \( ES \).

**Proof.** Mechanized in Agda.

In the remainder of this section, we consider an example logic. Let \( T \) be a set of type names, ranged over by \( \tau \). The set \( \Phi \) of formulae is generated by the following BNF.

\[
\phi, \psi ::= x \neq v \mid x: \tau \mid \text{true} \mid \text{false} \mid \phi \land \psi \mid \phi \lor \psi
\]

Given a semantics \( V_{\tau} \subseteq V \) for each type \( \tau \), let \( \models \) be the obvious satisfaction relation generated by the following rules for the atoms.

- \( A \models x \neq v \) when for any \( a \in A \), if \( a = (Rxw) \) or \( a = (Wxw) \), then \( w \neq v \).
- \( A \models x: \tau \) when for any \( a \in A \), if \( a = (Rxv) \) or \( a = (Wxv) \), then \( v \in V_{\tau} \).

Note that the logic is satisfiable and subset closed and thus satisfies the criteria of Theorem 5.1.

Suppose that we attempt to show that \( \phi_1 = (x \neq 1 \land y \neq 1) \) is a tautology for \( P_1 \). Recall the event structure for this program, given in the introduction.

\[
(y = x; \ || x = y;)
\]
Note that any configuration which includes write events 16 or 18, must also include read events 12 or 14. Thus, if the read events satisfy $\phi_1$ then the write events satisfy $\phi_1$, and so $\phi_1$ is invariant for $P_1$. Thus, by Theorem 5.1, $\phi_1$ is a tautology for $P_1$.

For $P_3$, instead, $\phi_1$ fails. Recall the event structure for this program, also given in the introduction.

\[(r=x; y=1; \| x=y;)\]

The configuration \{30, 31, 35\} fails to satisfy $\phi_1$ even though its only read event 31 satisfies $\phi_1$.

These examples can be adapted to show reasoning using types. Let 0 be the unique value of type Unit. Then $P_1$ satisfies the typing $x: \text{Unit} \land y: \text{Unit}$, but $P_2$ does not.

6. Fencing

In §3, we noted that a memory alphabet includes synchronized justification, such as lock release and acquire; however, we have not made any use of synchronization up to now. In this section, we develop a notion of fencing, in which synchronized justifications contribute to causal order.

We model lock-based synchronization in a very simple setting. We assume that there is only one, statically allocated lock and that lock release always occurs in the same thread as the previous acquire. The latter assumption ensures that each release causally follows the corresponding acquire.

The memory alphabet from §3 is modified to include acquire and release actions, which are considered both read and write actions. (We comment on this design in §9.)

$$\Sigma = R \cup W$$

$$R = \{(R x v), Aq, RI \mid x \in X, v \in V\}$$

$$W = \{(W x v), Aq, RI \mid x \in X, v \in V\} \cup \{\text{init}\}$$

The semantics of locking actions are as follows.

$$T[\text{acq};T]_\rho \triangleq Aq \bullet T[T]_\rho$$

$$T[\text{rel};T]_\rho \triangleq RI \bullet T[T]_\rho$$

The justification relation, $J$, now includes lock actions:

$$J = \{(\text{init}, (R x 0)), ((W x v), (R x v)) \mid x \in X, v \in V\}$$

$$\cup \{(\text{init}, Aq), (Aq, RI), (RI, Aq)\}$$
The synchronized justification relation, \( K \), is restricted to lock actions.

\[
K = \{(\text{init}, Aq), (Aq, Rl), (Rl, Aq)\}
\]

Recall from §3 that event \( d \) justifies event \( e \) whenever (1) \( (\lambda(d), \lambda(e)) \in J \), (2) \( d \) does not follow \( e \), (3) \( d \) is not in conflict with \( e \), and (4) there is no intervening \( b \) between \( d \) and \( e \) that justifies an event in primitive conflict with \( e \).

We say event \( d \) synchronously justifies event \( e \) whenever \( d \) justifies \( e \) and \( (\lambda(d), \lambda(e)) \in K \).

A fenced memory event structure is one where, for any events \( d \) and \( e \), if \( d \) synchronously justifies \( e \) then \( d \leq e \).

A well-fenced configuration of a memory event structure is a well-justified configuration of a fenced augmentation of it. That is, a configuration \( C \) of \( ES \) is well-fenced if there exists a augmentation \( ES' \) of \( ES \) such that \( ES' \) is fenced and \( C \) is a justified configuration of \( ES' \).

To show that a configuration is well-fenced, the player must first augment the event structure so that it is fenced. Then the inductive argument for well-justification proceeds as before.

For example, consider the following program, \( P_5 \).

\[
\text{acq; } x=1; \text{ } x=0; \text{ rel; } || \text{ acq; } r=x; \text{ rel; } \quad (P_5)
\]

Whereas the second thread can read 1 in a well-justified configuration, this is not possible in a well-fenced configuration. There are two possible fencings. One includes the augmentation \( 57 \leq 52 \), and the other includes \( 58 \leq 51 \) and \( 59 \leq 51 \). In either case, 54 can be justified, but 55 cannot. Therefore, there is no well-fenced configuration that includes 55.

Note that any sequential memory event structure is fenced. It follows that any sequential augmentation of a memory event structure is a fenced augmentation of it, and hence that any sequentially consistent configuration is a well-fenced configuration.

Now, if every justification is synchronized (that is \( J = K \)) we have that every well-fenced configuration is sequentially consistent, but in general this is not true. In particular, if there is no synchronization (that is \( K = \emptyset \)) then every well-justified configuration is well-fenced.

Fortunately, the proof of the DRF Theorem for well-fenced configurations follows directly from the DRF theorem for well-justified configurations: we just use DRF on each fencing.

**Theorem 6.1 (DRF).** In any commutative read-enabled memory event structure, if all sequentially consistent configurations are data-race-free, then all well-fenced configurations are sequentially consistent.

**Proof.** Follows directly from Theorem 4.1. □
7. Limitations

As we noted in §3, one possible goal for a memory model is that an execution should be allowed if there exists an augmentation, such as thread inlining, that allows it. A related goal is that an execution should be allowed if it is allowed for a subset of threads. These are non-goals for our semantics, which, indeed, fails to validate them.

Both adding new threads and reducing causal order afford greater flexibility in choosing configurations. The additional flexibility can be exploited by the player, validating additional executions. But it can also be exploited by the opponent, eliminating executions that would be possible without the additional flexibility. Consider a variant of the program given in Example 3.5, which is similar to TC9 from [Pugh 2004]:

\[ r_1 = x; \text{if}(r_1 < 2)\{y = 1;\} || x = 2; || r_2 = y; x = r_2; \] (TC9')

Relative to Example 3.5, we have added a thread that writes 2 to x. To forbid configurations that include \((R_y 1)\), it is sufficient for the opponent to chose a configuration that includes \((W_x 2)\) and \((R_x 2)\); clearly such a configuration can be acyclically justified. This opponent move is unavailable, however, if the new thread is removed or if it is inlined after either of the other threads; in this case, \((R_y 1)\) is possible, following the reasoning of Example 3.5.

Of the remaining nineteen test cases from [Pugh 2004], our semantics disagrees with TC3, TC7 and TC11. In all cases, the reason is the same. We discuss TC7, which best elucidates the issues.

\[ r = z; y = x; || z = y; x = 1; \] (TC7)

The question is whether all of the reads can be resolved to 1. This fails under our semantics: there is no well-justified configuration that includes events c, e and i, all of which read 1. In order to well-justify such a configuration, one must first resolve the conflict on x, then y and finally z. But this strategy fails immediately after resolving x.

Starting from the empty configuration, all acyclically justified configurations can be extended to include either p or q, and thus the player can select a configuration that includes either q or i. Suppose the player selects i. Since configurations are downclosed, the player must also select c; however c is not acyclically justified when the opponent selects p. Symmetrically, b is not acyclically justified when the opponent selects q. Thus the player cannot resolve the conflict on y.

The failure of TC7 indicates a failure to validate the reordering of independent reads. To see this, consider the program in which the first thread is rewritten.

\[ y = x; r = z; || z = y; x = 1; \]
In this case, the player can choose $c'$, then $e'$, then $o'$, as required.

We now sketch a proposal to address this issue. On sets of events, define $C$ is compatible with $D$ whenever there is no $c \in C$ and $d \in D$ such that $c \#_\mu d$. Define $C$ is consistent whenever $C$ is compatible with $C$.

**Proposal 7.1.** Modify Definitions 3.2 and 3.3 to range over consistent sets, rather than configurations.

A configuration $C$ is *alt-well-justified* whenever $C$ is justified and there exists a consistent set $D$ such that $\emptyset \subseteq^* D \supseteq C$.

By this proposal, the definition of alt-AE-justifies is as follows: On consistent sets, $C$ *alt-AE-justifies* $D$ whenever for any $C \preceq^* C'$ there exists a $C' \preceq^* C''$ such that $C''$ justifies $D$.

The configuration of TC7 that always reads 1 is alt-well-justified. Starting from the empty set, $C_1 = \{a, g, i\}$ is alt-AE-justified, since every consistent set that extends $\emptyset$ (via $\subseteq^*$) can be further extended to include either $p$ or $q$, both labeled ($Wx_1$). Although $g$ and $i$ are in conflict, they are not in primitive conflict, and therefore may both be included in a consistent set—this is the key difference between well- and alt-well-justification. From $C_1$, $C_2 = \{a, g, i, e\}$ is alt-AE-justified, since we can always extend to include either $m$ or $o$, both labeled ($Wy_1$). From $C_2$, $C_3 = \{a, g, i, e, c\}$ is alt-AE-justified, since we can always extend to include $k$, labeled ($Wz_1$). Thus $\emptyset \subseteq^* C_3$ and therefore, since writes do not require justification, $\emptyset \subseteq^* \{a, g, m, i, o, e, k, q, c\} \supseteq \{a, i, o, e, k, q, c\}$, as required.

By hand calculation, alt-well-justification agrees with all nineteen test cases; therefore, the definition looks quite promising. The question of whether DRF holds for alt-well-justification remains open. The inductive structure of the proof of DRF relies on the fact that configurations are down closed. Since consistent sets are not necessarily down closed, the proof strategy fails.

8. Related work

Our model is inspired by the Java Memory Model, first described by Manson et al. [2005] and explored by Ševčík [2008]. Lochbihler [2013] provides mechanized proofs, in addition to an encyclopedic survey and history.

The use of universal quantification over configurations in the definition of AE-justification is novel in this work. Prior definitions for Java-like languages are purely existential in their quantification over possible executions [Manson et al. 2005; Cenciarelli et al. 2007; Jagadeesan et al. 2010]. This leads to differences between our model the JMM, such as the execution of Example 3.7, which is allowed in our model, but disallowed by the JMM [Ševčík 2008, §5.3.2].

Batty et al. [2015] describe the problem of thin-air executions and provide a detailed review of the literature. They show the limitations of syntactic notions of dependency, as
defined, for example, in C++ [Boehm and Adve 2008; Batty et al. 2011]. In particular, for C++ they show that there is no per-candidate-execution condition that precludes thin-air reads while allowing sufficient optimization. This problem is avoided in hardware models, such as [Alglave 2010; Alglave et al. 2014], which are not subject to compiler optimization and therefore can encode the specific notion of dependency provided by the hardware at hand.

Event structures have appeared in other attempts to formalize relaxed memory semantics:

- Our first attempt to model relaxed memory using labeled prime event structures was presented at a workshop in Cambridge [Jeffrey and Riely 2014]. Our proposal was to allow configurations that are relaxed justified: Define a pre-configuration to be a \( \leq \)-downclosed set of events. A pre-configuration is relaxed justified when it has a total order such that any non-initial event has a justifier that precedes it in the total order. A justified configuration is relaxed justified when it is included in a relaxed justified pre-configuration. We abandoned this approach after Sezgin [2014] discovered that the program \((y=x+1; \ | \ | x=y;)\) may generate any integer under this model. This example is since referred to as the Random Number Generator (RNG).

- Pichon-Pharabod and Sewell [2016] defined a semantics for C/C++ relaxed atomics using event structures to model the state of a single thread, with the goal of providing an semantic model of single-threaded optimization. Deordering allows removal causal order between events of a thread that are not causally related; for example, replacing \(r=x;y=1\) with \(r=x \ | \ | y=1\). Merging allows collapsing redundant reads into a single event; for example, replacing \(r1=x;r2=x;C\) with \(r1=x;C'\), where \(C'\) is derived from \(C\) by replacing occurrences of \(r2\) by \(r1\). Kang et al. [2017] observe that this model is not robust with respect to all of the relaxations permitted under hardware models.

- Castellan [2016] presented a semantics for relaxed memory using event structures and a restricted form of interleaving. In this work, the open semantics of processes is as one expects for an event structure, with parallel processes unordered by causality. In the closed semantics, all events on the same memory cell are related by either conflict or causality. Although interleaving is only required for events on the same memory cell, the process of computing the semantics may cause an exponential increase in the state space.

These works can be classified by the role of universal quantification: Pichon-Pharabod and Sewell use universal quantification to define deordering. Castellan uses it to define interleaving. We define AE-justification using universal quantification over the possible moves of the opponent.

Unique among these work, we use the standard denotational semantics of parallel composition for event structures.

Since the initial publication of this paper, Chakraborty and Vafeiadis [2017] defined an operational semantics for a subset of LLVM, which they extended in 2019. This semantics uses “event structures” to record potentially conflicting operational steps — these are close in spirit to the pre-configurations of [Jeffrey and Riely 2014]. As a result, this model is susceptible to the bad RNG execution discussed above. To avoid it, Chakraborty and Vafeiadis restrict attention to pre-configurations where all events are visible: event \(e\) is visible if for every write that precedes \(e\) in causal+justification order, there is a write with the same label that does not conflict with \(e\).
Cooksey et al. [2018] showed how to simulate several memory models using fragments of second order logic. They formalized our model and used a mechanized solver to validate several examples. In particular, they studied the following program:

\[ y = x; \parallel z = 1; \parallel \text{if}(\neg z) \{ x = y; \} \text{else} \{ x = 1; \} \]

\[(P_6)\]

Cooksey et al. have established that there is no well-justified configuration of \( P_6 \) that includes both \((Rz_0)\) and either \((Rx_1)\) or \((Ry_1)\). The rationale for forbidding this execution is similar to that for TC5: Pugh [2004] states that “values are not allowed to come out of thin air, even if there are other executions in which the thin-air value would have been written to that variable by some not out-of-thin air means.”

### 9. Open Problems

As far as we are aware, it remains an open problem to define a sensible semantics that allows the behavior of TC9’ from §7 while disallowing that of \( P_6 \) from §8. Our model disallows TC9’. Speculative models that rely on purely existential reasoning allow \( P_6 \); this includes the models of Manson et al. [2005], Jagadeesan et al. [2010], Kang et al. [2017] and Chakraborty and Vafeiadis [2019].

**Coherence** is the property that writes on a single variable appear to occur in some global order. Our model does enforce coherence on synchronization variables, where justification implies causal order, but not on plain variables. For example, in a coherent semantics for \((x=1;) \parallel (x=2;) \parallel (r_1=x; r_2=x; r_3=x;)\) it is not possible to have \(r_1 = r_3 \neq r_2\), whereas our semantics allows this. Our model is not unique in this respect: This outcome is allowed by the JMM [Manson et al. 2005] and by the Local DRF model of [Dolan et al. 2018]; C++ gives undefined behavior for this program. To enforce coherence on plain variables, it appears to be necessary to distinguish the causal order from the order used to determine visibility.

We have modeled synchronization using a restricted form of locks. A coherent semantics is required to model Java’s volatile variables, and would also allow a more satisfactory treatment of locks. In the formalization of §6, release and acquire are both read/write actions. This guarantees that, for example, a single release does not enable two parallel acquires. In the standard treatment of locks, assuming coherence, release is a write, and acquire is a read; thus, release justifies acquire, but acquire does not justify release. The order between acquire and release is usually guaranteed by thread order, which we have assumed. This assumption guarantees that the order we have required from acquire to release is redundant. With a coherent semantics for locks, the causal order from acquire to release can be dropped.

Separate from the concerns of §7, variations on the definition of well-justification may be worth exploring. For example, we define \( \sqsubseteq^* \) in terms of \( \sqsubseteq^* \): when exploring extensions of the current configuration, both player and opponent are restricted to using acyclic
justification. It is natural to ask about a further definition, which uses $\sqsubseteq^*$ in place of $\preceq^*$. If we let $\sqsubseteq_i^0 = \preceq_i^*$ and $\sqsubseteq_i^1 = \sqsubseteq_i^*$, we can see this as a hierarchy where each $\sqsubseteq_i^*$ uses $\sqsubseteq_{i-1}^*$. It is not the case that $\sqsubseteq_i^*$ contains $\sqsubseteq_{i-1}^*$, since the definition uses $\sqsubseteq_{i-1}^*$ in both positive and negative position: positive for the player, and negative for the opponent. Example 3.7 is interesting in this regard. If the opponent is allowed to pick using $\text{AE}$-justification, then the player is unable to well-justify the desired configuration. Well-justification becomes possible, however, if the opponent is restricted to acyclically chosen configurations.

We have investigated a very simple program logic, which establishes a restricted form of safety. It would be interesting to investigate more powerful logics, such as that of Turon et al. [2014]. One of the primary purposes of a memory model is to support program transformation. To this end, it would be useful to have a refinement relation over memory event structures that preserves well-justification.

Our approach to type safety is novel, in that we have not required a static association between variables and types as in prior work [Lochbihler 2013; Goto et al. 2012]. It would be interesting to extend our approach to model dynamic allocation and deallocation.

ACKNOWLEDGEMENT

The paper have benefited from discussion with JMM working group and the anonymous referees.

In an earlier version of this paper, Definition 3.2 of acyclic justification quantified over $d \in D$ rather than $d \in D \setminus C$. The new definition was suggested by Simon Cooksey and Mark Batty by email in April, 2019. They noted that Example 3.5 failed under the original definition, since the player configuration $C_3$ is not acyclicly justified by $C_2$, which is a valid opponent move.
