(Dated: October 30, 2017)

The magnetic oscillations in YBCO high-temperature superconductors have been widely studied over the last decade and consist of three equidistant low frequencies with a central frequency several times more intense than its two shoulders. This remains a puzzle in spite of numerous attempts to explain the corresponding small Fermi-surface pockets. Furthermore the ARPES data indicate only four Fermi-arcs with bilayer splitting, and show no sign of such small areas in the Fermi surface. Here we argue that the magnetic oscillations measured in under-doped bilayer high temperature superconductors, in particular YBa\textsubscript{2}Cu\textsubscript{3}O\textsubscript{6+δ}, provide a measure of the interplanar electronic coupling rather than the areas of fine-grain reconstruction of the Fermi surfaces coming from induced charge density waves. This identification is based on the relative intensities of the different peaks, as well as their angular dependence, which points to an effective Fermi surface that is larger than the oscillation frequencies, and is compatible with several indications from ARPES. The dominance of such frequencies with respect to the fundamental frequencies from the Fermi surface is natural for a strongly correlated quasi-two dimensional electronic systems where non-linear mixings of frequencies are more resistant to sample inhomogeneity.

I. INTRODUCTION

Magnetic quantum oscillations (MQO) is a traditional and powerful tool to study electronic structure of various metals\textsuperscript{1–3}. The first observation of MQO in cuprate high-temperature superconductors about a decade ago\textsuperscript{4} was rather a surprise given that these are normally taken as indicating a Fermi surface of a normal metallic state. Since then, MQO have been used extensively to investigate the electronic structure in cuprates, both hole-doped\textsuperscript{5–8} and electron-doped\textsuperscript{9–12}, as well as in various Fe-based superconductors\textsuperscript{13–19}. Probably the most striking data are for the underdoped yttrium barium copper oxide (YBCO) compounds YBa\textsubscript{2}Cu\textsubscript{3}O\textsubscript{6+δ}, reviewed in\textsuperscript{20–22}, where there is one prominent oscillation peak at frequency \(F_\alpha \approx 530T\) with two smaller shoulders at \(F_k = F_\alpha \pm \Delta F_\alpha\), where \(\Delta F_\alpha \approx 90T\). All three frequencies in YBCO are much smaller than expected from closed pockets of any Fermi surface, seen, for example from ARPES experiments\textsuperscript{22,29}.

The completely unreconstructed Fermi surface of YBCO would consist of one large pocket, almost a square with smoothed corners, filling about one half of the Brillouin zone and corresponding to a large frequency \(10^4\) tesla. Fermi-surface reconstruction, possibly caused by the pseudogap, AFM or CDW order, takes place for doping level \(p < 15\%\), resulting to four Fermi arcs, as suggested by ARPES\textsuperscript{28,29} and schematically shown in Fig. 1. The scattering by the AFM wave vector \(Q = (\pi/a, \pi/b)\), connecting the ends of Fermi arcs, forms closed FS pockets of area about 6\% of the Brillouin zone, corresponding to MQO frequency about 1.6kTesla. The observed magnetic oscillation frequency \(F_\alpha \approx 530T\) corresponds to a Fermi-surface cross-section of only 2\% of the Brillouin zone, much less than the size of the pockets suggested by ARPES, without entering into considerations such as whether the "Fermi arcs" can actually be closed. Thus there is a clear inconsistency between the ARPES and MQO experimental data. An unusual alternative source of oscillations was proposed in terms of Andreev-type bound states\textsuperscript{23} but the predicted change in oscillation frequencies with superconducting gap contradicts experiment.

The situation has been complicated by the subsequent evidence of at least fluctuating and short range charge order in low fields by X-ray scattering\textsuperscript{30,31} nuclear magnetic resonance\textsuperscript{32–34}, and sound velocity measurements\textsuperscript{35}. In the high magnetic fields corresponding to the range where magnetic oscillations are observed, superconductivity is gradually suppressed and charge density wave coherence is stabilized\textsuperscript{36}. The measured Hall and Seebeck coefficients\textsuperscript{37,38}, treated by the simplified theory without taking into account magnetic breakdown, strong electronic correlations and superconducting flux flow contribution, support additional Fermi-surface reconstruction. Thus it is tempting, but we argue misleading, to attempt to explain the observed low-frequency magnetic oscillations by the appearance of new Fermi surface pockets coming from reconstruction of the larger Fermi surfaces by charge density wave order. Different attempts in this direction vary in details such as inclusion of spin-orbit or Zeeman splittings\textsuperscript{39–41} but it is hard to explain the observed three-peak frequency pattern of quantum oscillations.
tions without predicting additional frequencies of similar amplitudes from the charge order. Note that a frequency pattern somewhat similar to that of YBa$_2$Cu$_3$O$_{6+\delta}$ is observed in the closely related stoichiometric compound YBa$_2$Cu$_4$O$_8$ where there is no indication of a static superstructure. Furthermore if very small Fermi-surface pockets really are the origin of the observed $F_\alpha$, $F_\beta$, and $F_\gamma$ frequencies, they should depend strongly on doping which does not seem to be the case: for instance $F_\alpha$ changes by only 10% when the doping $p$ almost doubles, from 0.09 to 0.14.

In this paper, we argue that the magnetic oscillations in these under-doped bilayer high temperature superconductors in fact provide a measure of the inter-planar electronic coupling and do not, contrary to widespread belief, correspond to areas of fine-grain reconstruction of the Fermi surfaces coming from induced charge density waves. This identification is based on the relative intensities of the different peaks, as well as their angular dependence, which points to an effective Fermi surface that is larger than the oscillation frequencies, and is compatible with indications from ARPES as to the fundamental frequency as well as the bilayer splitting. The dominance of such frequencies with respect to the standard frequencies from the Fermi surface, whose current observation is still somewhat controversial, is natural because the non-linear mixings of frequencies better survive sample inhomogeneity, as we show in detail below.

II. MAGNETIC OSCILLATION PRODUCED BY INTERLAYER HOPPING

A. Qualitative idea

A clue to the origin of the observed tiny MQO frequencies comes from what are called “slow oscillations” (SIO) in organic superconductors. In these quasi-two dimensional compounds, oscillations can be clearly attributed, after no little debate, not to new small pockets of the Fermi surface, but to the mixing of two close frequencies $F_\beta \pm \Delta F$, where only the $F_\beta$ frequency corresponds to a Fermi-surface area and the frequency splitting $\Delta F$ is due to Fermi-surface warping, whose origin is the interlayer electron transfer integral $t_z$. Magnetoresistance (MR) oscillations with a much lower beat frequency $F_{\text{slow}} = 2\Delta F = 4t_z B / h \omega_c$ then arise. What is surprising at first sight is that the amplitude of such emergent slow oscillations is much higher than those of the oscillations with the original frequencies $F_\beta \pm \Delta F$, because they are damped neither by temperature nor by long-range disorder (spatial inhomogeneity, leading to variations of $E_F$ along the sample on the scale much larger than magnetic length) (see Sec. IID below). Even in high-quality monocrystals of organic metals such long-range disorder has been shown to make the major contribution to the Dingle temperature. In the notoriously inhomogeneous cuprates, such disorder is undoubtedly much stronger, and magnetic oscillations from closed pockets should be even more strongly damped compared to the beat frequencies.

To pursue this basic idea, we here extend the theory developed for the organics to include interplanar couplings from the underlying bilayer structure of YBCO, illustrated in Fig. 1. The richer structure that emerges will, in fact, give a much clearer indication of the origin of the low-frequency oscillations. In a bilayer structure there are two types of interlayer hopping: (i) between adjacent layers separated by distance $d$ within one bilayer, given by the transfer integral $t_\perp = t_\perp (k \parallel)$, and (ii) between adjacent equivalent bilayers separated by distance $h$, given by the transfer integral $t_z = t_z (k \parallel)$, where $k \parallel$ is the intralayer momentum. The resulting electron energy
This electron energy spectrum has, for \( t_z \ll t_\perp \), bonding and anti-bonding states each with weak \( \varepsilon \) dispersion and separated by \( \sim 2 t_\perp (k_\parallel) \):

\[
e_\pm (k_z, k_\parallel) = e_\parallel (k_\parallel) \pm \sqrt{t_z^2 + t_\perp^2 + 2t_z t_\perp \cos [k_z (h + d)]}. \tag{1}
\]

This electron energy spectrum has, for \( t_z \ll t_\perp \), bonding and anti-bonding states each with weak \( \varepsilon \) dispersion and separated by \( \sim 2 t_\perp (k_\parallel) \):

\[
e_\pm (k_z, k_\parallel) \approx e_\parallel (k_\parallel) \pm 2t_\perp (k_\parallel) \cos [k_z (h + d)]. \tag{2}
\]

The corresponding in-plane Fermi surface, shown schematically in Fig. 1, contains four split Fermi arcs shown by green lines for bonding and by red lines for antibonding states, in agreement with ARPES data.\(^{28,29}\) The dashed lines in Fig. 1 denote the Fermi arcs shifted by the vector \( Q \approx (\pi/a, \pi/b) \), which correspond to the reconstructed Fermi surface due to scattering by AFM and pseudogap ordering. These dashed lines together with solid lines form two closed Fermi-surface pockets of slightly different area, which may produce MQO. According to our proposal, the doubled difference between the bonding (green) and antibonding (red) pockets gives the slow \( F_\alpha \approx 530 T \) MQO frequency observed in YBCO. The two side frequencies come from 3D warping of these FS pockets, illustrated in Fig. 1 and originating from interlayer electron hopping \( t_z \), corresponding to the last term in Eq. (2). This interpretation is supported by the observed angular dependence of the \( \Delta F_\alpha \) splitting.\(^{24}\) Below we give a more quantitative and detailed substantiation of our interpretation.

### B. Analytical formula for slow magnetoresistance oscillations

According to Eq. (2), in YBCO there should be at least two types of splitting of the original frequencies: the larger bilayer splitting \( \Delta F_\perp = t_\perp B / \hbar \omega_c \), where \( t_\perp = \langle t_\perp (k_\parallel) \rangle \neq 0 \) and the angular brackets signify an averaging over in-plane momentum \( k_\parallel \) on the Fermi surface, and the smaller splitting \( \Delta F_\parallel = 2t_z B / \hbar \omega_c \ll \Delta F_\perp \ll F_\beta \) due to the \( k_z \)-electron dispersion, where we also assume \( t_z = \langle t_z (k_\parallel) \rangle \neq 0 \). These two splittings result in four underlying frequencies \( F_\beta \pm \Delta F_\perp \pm \Delta F_\parallel \) of similar amplitudes. The slow oscillations in magnetoresistance originate from these four frequencies result in a much richer set of frequencies than for a single layer structures previously considered, which had only two \( F_\beta \pm \Delta F_\parallel \).\(^{21,54}\)

The metallic conductivity along \( i \)-th axis \( \sigma_i = \sigma_{ii} \) is given by the sum of contributions from all ungapped pockets \( \beta \) and over two spin components \( s \):

\[
\sigma_i = \sum_{\beta, s} \sigma_{i, \beta, s} = \sum_{\beta, s} e^2 g_{\beta \beta} D_{i, \beta}. \tag{3}
\]

At low temperature each pocket \( \beta \) contributes to the total metallic conductivity along axis \( i \) at low temperature via the product of a density of electron states (DoS) \( g_{\beta \beta} = g_3 (\varepsilon = E_\beta) \) and an electron diffusion coefficient \( D_{i, \beta} \). Both contribute to oscillations, since they vary with the magnetic field \( B \) perpendicular to the conducting \( x-y \) layers.\(^{35}\) (see Appendix A for a detailed derivation)

\[
\frac{g_{F, \beta}}{g_0} = 1 - \sum_{l = \pm 1} 2J_0 \left( 2\pi \frac{\Delta F_\perp}{B_2} \right) \cos \left( 2\pi \frac{F_\beta - l \Delta F_\perp}{B_2} \right) R_D,
\]

where \( R_D = \exp (-2\pi^2 T_D / \hbar \omega_c) \) is the Dingle factor,\(^{24}\) and

\[
\frac{D_{i, \beta}}{D_{0i, \beta}} = 1 + B_{i, \beta} \sum_{l = \pm 1} J_0 \left( 2\pi \frac{\Delta F_\perp}{B_2} \right) \cos \left( 2\pi \frac{F_\beta - l \Delta F_\perp}{B_2} \right) R_D.
\]

Substituting Eqs. (4), (5) into Eq. (3) one obtains four types of oscillating terms: (i) the first harmonics, of first order in \( R_D \) and oscillating rapidly at frequencies \( \sim F_\beta \); (ii) the second harmonics with amplitude \( \sim R^2_D \) and frequency \( \sim 2F_\beta \); (iii) “Ultra-slow” oscillations

\[
\sigma_{USLO} (B_z) \propto J^2_0 (2\pi \Delta F_\perp / B_2) R^2_D
\]

with frequency \( \sim 2 \Delta F_\perp \); and (iv) “Slow” oscillations with frequency \( \sim 2 \Delta F_\perp \left( \varepsilon = E_\beta \right) \).

The Fourier transform (FT) of this magnetic-field dependence of \( \sigma_{USLO} (B_z) \) is shown in Fig. 2. It closely resembles the experimental data in YBCO.\(^{26,24}\) There are three qaudistant harmonics, and the amplitudes of the side peaks relative to the central decrease both with the Dingle factor \( R_D \) and with a reduction of the field interval available in experiment.

### C. Temperature dependence of slow magnetoresistance oscillations

At finite temperature \( T \) the conductivity tensor is

\[
\sigma (T) = \int d\varepsilon [-n_F (\varepsilon)] \sigma (\varepsilon), \tag{8}
\]

where the derivative of the Fermi distribution function \( n_F (\varepsilon) = -1 / (4T \cosh^2 (\varepsilon - \mu) / 2T) \), and \( \sigma_{ij} (\varepsilon) \) is the component of the electron conductivity tensor at energy \( \varepsilon \). Usual magnetic oscillation come from the first-order terms in the Dingle factor, such as \( g_{F, \beta} (\varepsilon) / g_0 \varepsilon \), which oscillate rapidly as a function of energy \( \varepsilon \):

\[
\frac{\sigma_1 (\varepsilon)}{\sigma_0} \propto 2J_0 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) R_D \sum_{l = \pm} \cos \left( 2\pi \frac{\varepsilon \pm t_z}{\hbar \omega_c} \right), \tag{9}
\]

where \( \sigma_0 \) is the non-oscillating part of conductivity. Substituting Eq. (9) into Eq. (8) and performing the integration over \( \varepsilon \), one obtains the well-known result that at finite temperature the MQO are dumped by the factor

\[
R_T = (2\pi^2 k_B T / \hbar \omega_c) / \sinh (2\pi^2 k_B T / \hbar \omega_c), \tag{10}
\]
Dingle temperatures form of magnetic oscillations given by Eq. (7) at four different

The Fourier transform of magnetic oscillations in quasi-2D conductor with bilayer splitting.

(a) The Fourier transform of magnetic oscillations in Eq. (7) at $T < B_D$ (green line). Insert shows the initial function $\sigma_0$ at $\pi T_0/\hbar \omega_c (B_z = 1T) = 1$ (dashed black line), $3$ (solid blue line), $5$ (dotted red line) and $7$ (dash-dotted green line). Insert shows the initial function $\sigma_{SIO} (1/B_z)$ at $\pi T_D/\hbar \omega_c (B_z = 1T) = 3$. (b) The Fourier transform of conductivity in Eq. (4) at $T_D = 0$ but in the finite field intervals $20T < B_z < 100T$ (solid black line), $20T < B_z < 65T$ (dashed green line), $25T < B_z < 65T$ (dotted red line), and $30T < B_z < 65T$ (dotted red line).

which gives

$$\frac{\sigma_1 (\mu)}{\sigma_0} \propto 2 J_0 \left( \frac{4 \pi t_\perp}{\hbar \omega_c} \right) \cos \left( 2 \pi \frac{\mu + t_\parallel}{\hbar \omega_c} \right) R_D R_T \quad (11)$$

$$= 2 J_0 \left( \frac{2 \pi \Delta F_c}{B_z} \right) \sum_{l=\pm 1} \cos \left( 2 \pi F_\parallel - l \Delta F_\perp / B_z \right) R_D R_T.$$

The slow oscillations come from the product of oscillating quantities, such as $(g_{F,\parallel} (\varepsilon) / g_{F,\perp})^2$, which for bilayer-split electron dispersion in Eq. (2) in the second order in $R_D$ gives

$$\sigma_2 (\varepsilon) \propto 4 J_0^2 \left( \frac{4 \pi t_\perp}{\hbar \omega_c} \right) \cos \left( 2 \pi \frac{\varepsilon - t_\parallel}{\hbar \omega_c} \right) \cos \left( 2 \pi \frac{\varepsilon + t_\parallel}{\hbar \omega_c} \right) R_D^2$$

$$= 2 J_0^2 \left( \frac{4 \pi t_\perp}{\hbar \omega_c} \right) \cos \left( \frac{4 \pi \varepsilon}{\hbar \omega_c} \right) \cos \left( \frac{4 \pi t_\parallel}{\hbar \omega_c} \right) R_D^2 \quad (12)$$

The first term in the square brackets gives the second harmonic of MQO, which is strongly damped by temperature by the factor close to the square of $R_T$ in Eq. (4) similarly to the first harmonic. The second term in the square brackets of Eq. (12) responsible for SIO, is independent of energy. Therefore, its integration over $\varepsilon$ with $n_F (\varepsilon)$ in Eq. (5) does not produce any temperature damping factor for SIO:

$$\sigma_2 (\mu) \propto J_0^2 \left( \frac{4 \pi t_\perp}{\hbar \omega_c} \right) \left[ \cos \left( \frac{4 \pi \mu}{\hbar \omega_c} \right) R_D^2 + \cos \left( \frac{4 \pi t_\parallel}{\hbar \omega_c} \right) \right] R_D^2. \quad (13)$$

Thus, within this simplest model, the SIO are not damped by temperature, as seen in the observed slow oscillations in Refs. 21,22. However, magnetoresistance oscillations observed at frequency $F_o \approx 530T$ have some temperature damping, corresponding to an effective mass of $m^* \approx 1.6 m_e$.22,24,63 Such a strong temperature damping of what are proposed by us as being slow oscillations may arise from the square of the temperature-dependent Dingle factor $R_D$. For non-interacting electrons, the Dingle factor comes only from impurity scattering, $R_D$ is almost temperature independent. A weak electron-phonon interaction was also predicted65 not to violate the usual $R_T (T)$ to the lowest-order perturbation theory, but for YBCO at $T \sim 10K$ the electron-phonon interaction is not weak, and the result of Ref. 26 may not apply. In addition, the electron-electron interaction, which in cuprates is very strong, gives considerable temperature dependence to $R_D$, as observed experimentally and may contribute to the measured effective electron mass $m^* \approx 1.6 m_e$. Note that the extracted effective mass depends strongly on doping outside the doping interval $0.1 < p < 0.125$ and this would reflect the doping dependence of the strength of e-e interactions.

D. Effect of macroscopic spatial inhomogeneities

The macroscopic spatial inhomogeneities affect MQO similarly to temperature, because they smear the Fermi level $\mu$ along the whole sample. To show explicitly, let us take the most common Gaussian distribution of the spatially fluctuating shift of Fermi level $\Delta \mu (r)$, given by the normalized weight

$$D (\Delta \mu) = \frac{1}{\sqrt{2 \pi W}} \exp \left[ \frac{-(\Delta \mu)^2}{2W^2} \right]. \quad (14)$$

In addition to the temperature smearing in Eq. (8), given by the integration over electron energy $\varepsilon$, conductivity acquires the coordinate smearing, given by the integration over the shift $\Delta \mu (r)$ of chemical potential weighted by Eq. (14):

$$\sigma = \int d\mu \sigma (\mu) D (\mu - \mu_0 - \Delta \mu), \quad (15)$$

where $\sigma (\mu)$ is given by the sum of first- and second-order terms given by Eqs. (11) and (13). The first-order terms
give the MQO

\[
\frac{\sigma_1}{\sigma_0} \propto \int d\mu D (\mu - \mu_0 - \Delta \mu) 2J_0 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) \times \cos \left( \frac{2\pi \mu \pm t_1}{\hbar \omega_c} \right) R_D R_T
\]
\[= 2J_0 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) \cos \left( \frac{2\pi \mu_0 \pm t_1}{\hbar \omega_c} \right) R_D R_T R_W. \tag{16} \]

Here the last damping factor

\[R_W = \exp \left( -2\pi^2 W^2 / \hbar^2 \omega_c^2 \right)\]

comes from the spatial variations of the Fermi level. The width \(W\) of this Gaussian distribution of Fermi level contributes to the total Dingle temperature \(T_D^{tot} \approx T_D^{imp} + T_D^{inh}\), where \(T_D^{inh} \approx W\). Note that the Gaussian Fermi-level smearing leads to the quadratic dependence of in\( R_W\) on magnetic field and on harmonic number, which was experimentally observed in high-quality samples of quasi-2D organic metals.

The second-order terms after substitution to Eq. (13) give

\[
\frac{\sigma_2}{\sigma_0} \propto \int d\mu D (\mu - \mu_0 - \Delta \mu) J_0 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) R_D^2 \times \left[ \cos \left( \frac{4\pi \mu_0}{\hbar \omega_c} \right) R_T^2 + \cos \left( \frac{4\pi t_1}{\hbar \omega_c} \right) \right]
\]
\[= \left[ \cos \left( \frac{4\pi \mu_0}{\hbar \omega_c} \right) R_T^2 R_W + \cos \left( \frac{4\pi t_1}{\hbar \omega_c} \right) \right] J_0 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) R_D^2. \tag{17} \]

We see, that the second harmonic acquires the enhanced damping factor \(R_D^2\) from the Fermi-level variations, while the slow oscillations remain unchanged.

As a result, the fast quantum oscillations are additionally damped by the Fermi-level variations, while the SIO are not affected by this type of disorder. Qualitatively, this can be described by a complex Dingle factor \(R_D^{tot} = R_D R_W\), or as a complex Dingle temperature \(T_D^{tot} \approx T_D + W.\) The first usual part of the Dingle factor \(R_D\) comes from short-range disorder, e.g. impurities, and enters both the usual fast MQO and SIO. The second part of the Dingle factor \(R_W\) comes from the smearing of the local Fermi level by macroscopic long-range inhomogeneities and enters only the fast MQO. In organic metals the second part of the Dingle temperature \(W\) turns out to be unexpectedly large, being more than four times larger than the first part \(T_D\), so that \(T_D^{tot} \approx 5.3T_D\), as was demonstrated from the experimental data on the field dependence of the amplitudes of both types of magnetic oscillations in \(\beta-(BEDT-TTF)_2\)IBr_2.

In cuprates, which are notoriously inhomogeneous, the difference between \(T_D^{tot}\) and \(T_D\) can be even larger. Using Eqs. (16) and (17) and neglecting the second harmonics \(\propto \cos \left( \frac{4\pi \mu_0}{\hbar \omega_c} \right)\) in Eq. (17), we can rewrite the conductivity \(\sigma = \sigma_1 (\mu) + \sigma_2 (\mu)\) as

\[
\frac{\sigma}{\sigma_0} = J_0 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) \sum_{i=\pm 1} \cos \left( \frac{2\pi \mu + 2i t_1}{\hbar \omega_c} \right) R_T R_D R_W
\]
\[+ J_0^2 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) \cos \left( \frac{4\pi t_z}{\hbar \omega_c} \right) R_D^2. \tag{18} \]

The first line describes usual MQO, probably \(F_\beta\) frequency in YBCO, while the second line describes SIO, i.e. \(F_\alpha\) and \(F_\alpha \pm DF\) frequencies in YBCO. The damping factor \(R_T R_D R_W\) of usual MQO is, probably, much stronger than the damping factor \(R_D^2\) of SIO, which explains why \(F_\beta\) frequency in YBCO is much weaker and more fragile than \(F_\alpha\) and even than \(F_\alpha \pm DF\) frequencies.

E. Angular dependence of the frequencies of slow magnetoresistance oscillations

The angular dependence of the split frequency \(2\Delta F_c\), proportional to \(t_z\), drastically differs from that of \(2\Delta F_{c'}\), related to the bilayer splitting \(t_{c'}\). The frequency \(2\Delta F_c\) \(\propto t_z\) has a strongly non-monotonic dependence on the tilt angle \(\theta\) of the magnetic field.

\[
\Delta F_c (\theta) = \Delta F_c (\theta = 0) J_0 \left( k_F c^* \tan \theta \right) / \cos \theta, \tag{19} \]

where \(c^* = 11.65 \text{Å}\) for YBCO) is the lattice constant in the interlayer \(z\)-direction, and \(k_F\) is the Fermi momentum. This angular dependence is the same as for the beat frequency of MQO in a quasi-2D metal, but differs strongly from the standard cosine dependence

\[
F (\theta) = F (\theta = 0) / \cos \theta, \tag{20} \]

typical for quasi-2D metals where the interplanar coupling is so small that the Fermi surface can be considered perfectly cylindrical. Eq. (19) has an obvious geometrical interpretation: the slightly warped Fermi surface has two extremal cross-sections \(S_{ext}\) perpendicular to the magnetic field \(B\), which become equal, to first order in \(t_z\), at some tilt angles \(\theta_{lam}\). In contrast \(2F_{c'}\) has the cosine angular dependence given by Eq. (20). To see this, consider the dispersion in Eq. (2) at \(t_z \ll t_{c'}\), corresponding to the Fermi surface in Fig. 4: The Fermi surface consists of two cylinders along the \(z\)-axis with base areas \(S_{even}\) and \(S_{odd}\), differing by \(\Delta S = S_{even} - S_{odd} = 4\pi t_{c'} c^* \text{const}\). In a tilted magnetic field the two corresponding extremal cross-section areas are \(S_{even,odd} = S_{even,odd} / \cos \theta\), leading directly to Eq. (20). Thus, according to our interpretation, the angular dependence of \(F_\alpha\) frequency from bilayer splitting obeys the usual cosine dependence given by Eq. (20), while the shift \(\Delta F_\alpha\) of shoulder frequencies obeys Eq. (19) in agreement with experimental data in Ref. 24.
III. DISCUSSION

In the previous section we have shown that the interlayer hopping may produce low-frequency magnetic oscillations, given by Eq. 7 and illustrated in Fig. 2. Although these slow oscillations contain usual Dingle factor squared, they may be much stronger than the usual MQO, because the latter are strongly damped by sample inhomogeneities (see Sec. IID) or by temperature (see Sec. IIC). The Fourier transform of these slow oscillations has a natural three-peak structure. The amplitude of the central frequency $2\Delta F_c$ is at least twice as large as the amplitudes of the side frequencies $2\Delta F_\perp \pm 2\Delta F_c$, as can be seen from pure combinatorics (see Appendix B for details). As given by Eq. 7 and shown in Fig. 2, the amplitudes of side peaks are additionally damped by the Dingle factor or due to the finite field range of available experimental data. This theoretical plot closely resembles the experimental data in YBCO, 5–7, 20–27. We therefore propose that the observed three-peak structure is due to the mixing of four frequencies $F_\beta \pm 2\Delta F_\perp \pm 2\Delta F_c$, formed by a fundamental frequency $F_\beta$ split by bilayer and interbilayer electron hopping integrals $t_\perp$ and $t_z$. Several terms come from this frequency mixing even in the lowest second order in Dingle factor. A half of these terms come from various sums of fundamental frequencies and correspond to the second harmonics of fundamental frequencies, being much weaker than MQO with fundamental frequencies appearing in the first order in Dingle factor. The second half of mixed frequencies correspond to the various differences of fundamental frequencies, which do not contain electron energy or Fermi level but only split energies. Hence, these oscillations are robust against sample inhomogeneities, and therefore are much more pronounced than the MQO with fundamental frequencies. Such oscillations are responsible for the observed three-peak Fourier transform. The corresponding analytical expression is given in Eq. 7.

The frequencies $F_\alpha = 2\Delta F_\perp \approx 530T = 2t_\perp B/\hbar \omega_c$ and $\Delta F_\alpha = 2\Delta F_c \approx 90T \approx 4t_z B/\hbar \omega_c$ provide an experimental measure of the values of bilayer $t_\perp$ and interbilayer $t_z$ average electron transfer integrals. The extracted bilayer splitting can also be compared to ARPES data. 20.

We summarize arguments for this new interpretation:

1. Frequency pattern. The multiple extra magnetic oscillation frequencies predicted from the scenario with Fermi surface reconstruction are missing in experiment 5–7, 8, 11, 15. In contrast, the proposed model predicts only the three peaks shown in Fig. 2. The only frequency with an amplitude comparable to the side peaks at $F_\alpha \pm \Delta F_\alpha$ would be even lower: $2\Delta F_c \approx 90T$. The corresponding analytical expression is given in Eq. 9. Such ultraslow oscillations could be detected only at low magnetic field $B_2 < 2\Delta F_c$, where they are strongly damped by the Dingle factor. In addition, these ultraslow oscillations are not exactly periodic in $1/B_2$, especially in high field $B_2 \sim \Delta F_c$, because the zeros of the Bessel’s function in Eq. 6 are not exactly equidistant. Nevertheless, such low-frequency magnetic oscillations have been observed recently 22 supporting the proposed interpretation. Our model also predicts a much larger frequency $F_\beta$ from true Fermi surface pockets but with much smaller amplitude and much stronger damped by temperature and spatial inhomogeneities. Experimentally, the $F_\beta \approx 1.65kT$ frequency was indeed observed in dHvA 20 and Tunnel Diode Oscillation cyclotron resonance 22 measurements, but only at very low temperatures and not in all samples. 20.

2. Agreement with ARPES. The value of the bilayer splitting $\Delta B_S = 0.075\,A^{-1}$ in momentum space observed by ARPES 20 is consistent with the $F_\alpha = 2\Delta F_\perp \approx 530T$ frequency, corresponding to the FS area $S_\alpha = 0.0507\,A^{-1} \approx 2\% \cdot S_{BZ}$. According to our interpretation, it is the doubled shaded area between the bonding and antibonding Fermi arcs (see Fig. 3), given by the product $4\Delta B_S l_{FA}$, where $l_{FA} \approx 0.17\,A^{-1}$ is the length of a Fermi arc. The value of the average bilayer splitting $t_\perp$ expected from band-structure calculations 15, 18, 19 is also consistent with $F_\alpha \approx t_\perp \approx (t_\perp (k_\parallel)) = \hbar e F_\alpha / 2n_\parallel \sim 8\,meV$. Note that the maximum value $t_\perp (k_\parallel)$ of bilayer transfer integral may considerably exceed this average value $t_\perp$. Similarly the observed $t_z$-induced splitting $\Delta F_c \approx 90T \approx 4t_z B/\hbar \omega_c$ gives a reasonable average value $2t_z \approx 1.4\,meV$.

3. Doping dependence. The observed $F_\alpha \approx 530T$ depends weakly on the degree of doping 22, 23, 30, more consistent with our model than expected from tiny pockets in the Fermi-surface appearing due to FS reconstruction.

4. Damping by sample inhomogeneities. Long-range spatial inhomogeneities, common in cuprates, should strongly damp oscillations from true Fermi-surface pockets due to the smearing of Fermi level similar to the effect of temperature (see Secs. IID and IID). This type of disorder affects the proposed slow oscillations much less, as shown in Sec. IID, making their observation much easier.

5. The angular dependencies of the observed frequencies 22, 23 $F_\alpha$ and $\Delta F_\alpha$ agree with Eqs. 9 and 11 correspondingly. The observed strong angular dependence of the split frequency $\Delta F_\alpha (\theta)$ (see Fig. 4a in Ref. 22) is well fit by Eq. 13, suggesting that this frequency is indeed related to the $k_z$ electron dispersion, coming from the interlayer transfer integral $t_z$ and giving the warping of a larger Fermi surface. The extracted first Yamaji angle $\theta_{Yam} \approx 43^\circ$ in $\Delta F_\alpha (\theta)$, corresponding to the first zero of the Bessel function $J_0 (kp^* \tan \theta)$, indicates the Fermi momentum $kp^* = 2.4/c^* \tan \theta_{Yam} \approx 2.2\,nm^{-1}$ and a true Fermi-surface area of about $S_{ext} \sim \pi k_y^2 \approx 15\,nm^{-2}$. This corresponds to an underlying quantum oscillation frequency of $S_{ext} / 2\pi e \approx 1.6kT$ which is far from $F_\alpha \approx 530T$ but close to the reported value of $F_\beta \approx 1.65kT$ 20, 23. Note that $F_\beta$ was observed only at rather low temperatures and not in all samples. 22 which
is consistent with our model, because frequencies corresponding to real Fermi-surface pockets are stronger damped by sample-dependent inhomogeneities and by temperature than slow oscillations.

(6) Insensitivity to magnetic breakdown. A CDW-induced Fermi-surface reconstruction is not necessary for the observation of SI0. Hence, there are no issues to be resolved as how a weak and fluctuating CDW ordering, with transition temperature less than 40 K, overcomes the magnetic breakdown, which should be strong for fields up to 100 tesla and restore the electron orbits of unreconstructed Fermi surface.

(7) The relative amplitudes of the observed frequencies are naturally explained without additional fitting parameters (see Fig. 2).

Very similar magnetic oscillations have been observed in another closely related bilayer stoichiometric high-Tc superconductor HgBa2Cu3O6±δ. This compound has no indication of a CDW order, which excludes the CDW-induced fine-grained FS reconstruction giving small FS pockets. Hence, the proposed magnetic oscillations due to bilayer splitting is a quite general phenomenon. Not only cuprates but also rare-earth tritelluride compounds with bilayer crystal structure show similar slow oscillations originating from bilayer splitting, but the three-peak structure is not resolved there because of a very small value of \( t_z \). Similar slow oscillations with a frequency \( \approx 840 \text{T} \) (but without side-frequency splitting), corresponding to 3% of the Brillouin zone, have been observed in HgBa2CuO4+δ, where there is no bilayer splitting, but a much larger \( t_z \) is expected from the shorter interlayer distance. It is as yet unclear whether this frequency has the same origin, coming from \( t_z \), spin-orbit, magnetic or some other type of splitting. Therefore, a more detailed study of these magnetic oscillations, as well as the further theoretical study of this effect taking into account various types of electron-band splitting is needed.

To summarize, we propose and analyze a new interpretation of the observed magnetic oscillations in YBa2Cu3O6±δ high-Tc superconductors, with frequencies \( F_\alpha \approx 530 \text{T} \) and \( F_\alpha \pm \Delta F_\alpha \) related to the bilayer splitting and \( t_z \)-dispersion rather than to tiny Fermi-surface pockets. This is based on the new result 4, as illustrated in Fig. 2. The frequencies agree with ARPES data, thus resolving the long-standing puzzle, and allow us to estimate values of bilayer splitting \( t_z = \hbar F_\alpha /2m^* \) and of \( k_z \)-dispersion \( t_z = \hbar \Delta F_\alpha /4m^* \). The observed angular dependence of \( \Delta F_\alpha \) points to a true Fermi-surface pocket close to \( F_\beta \approx 1.6 kT \). This interpretation is robust, requiring only a bilayer crystal structure and a single-layer FS reconstruction, we cannot rule out the possibility of such reconstruction. Any new oscillations would be subject to magnetic breakdown, which depends on the strength of charge density order and the disorder. It would be important to quantify both aspects fully, by detailed study of charge order and magnetic oscillation as a function of doping and applied pressure, but it is likely that any new oscillations would be more fragile than the oscillations we describe. In our view, the bilayer geometry of YBCO is ideal in identifying the source of the oscillations that have been seen, but it could well be that in single-layer cuprates a similar mechanism can explain low frequency components.

The proposed model not only resolves the puzzle of inconsistency between ARPES and MQO data, but also suggests how the available extensive experimental data on MQO in YBCO can be used. According to our interpretation, the frequency of the observed slow magnetic oscillations in YBCO gives the area between bonding and antibonding Fermi-surface arcs much more precisely than can be obtained from ARPES data. The angular dependence of the observed shoulder frequencies allows to estimate the areas of the true Fermi-surface pockets, which may stimulate their reliable experimental observation. The comparison of the amplitudes of SI0 and true MQO would give the important information about the spatial variations of the Fermi level due to sample inhomogeneities. Our model also predict the magnetic oscillations with ultra-low frequency \( \sim 90 \text{T} \), which has an unusual angular dependence given by Eq. (19). Possibly such oscillations were detected in Ref. 22, but the angular dependence of their frequency needs further experimental study.

Appendix A: Density of states in quasi-2D metal with bilayer crystal structure

In a single-band quasi-2D metal without bilayer splitting with only one cylindrical Fermi Surface, an electron
displacement in the tight-binding approximation is
\[\epsilon(k_z,k_y) \approx \epsilon_{\parallel}(k_y) - 2t_z \cos(k_zc^*) .\]

In magnetic field \( B \) the electron spectrum consists of a set of equidistant Landau levels separated by \( \hbar \omega_c = \hbar e B_z/m^*c \), where \( m^* \) is the effective electron mass:
\[\epsilon_s(k_z,n) \approx \hbar \omega_c (n + 1/2) - 2t_z \cos(k_zc^*) + s \Delta_Z ,\]
where \( \Delta_Z = g \mu_B B \) is the Zeeman splitting, \( g \) is the g-factor, \( \mu_B \) is the Bohr magneton, and \( s = \pm 1/2 \) is the projection of quasiparticle spin on magnetic field \( B \), inclined by the angle \( \theta \) with respect to the normal to conducting layers. The corresponding oscillating density of electron states (DoS) \( g(\varepsilon) \) is given by the sum over Landau levels (LL):
\[g(\varepsilon) = \sum_{n=0}^{\infty} \sum_{k_z,s} \delta[\varepsilon - \epsilon_s(k_z,n)] \]
\[= \sum_{n=0}^{\infty} \sum_{s=\pm 1} g_{LL}/\pi \frac{g_{LL}/\pi}{\sqrt{4t_z^2 - (\varepsilon - s \Delta_Z - \hbar \omega_c (n + 1/2) + i \Gamma)^2}}.\]  

(A1)

where the LL degeneracy per unit area \( g_{LL} = eB_z/2\pi \hbar c \), and \( \Gamma = \Gamma(\varepsilon) \) is the broadening of electron levels due to scattering. It is often convenient to transform this sum over LL to the sum over harmonics using the Poisson summation formula. When MQO are weak, e.g. at \( \Gamma \gtrsim \hbar \omega_c \), keeping only the zeroth and first harmonics one obtains:
\[g(\varepsilon)/g_0 = 1 - 2J_0 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) \cos \left( \frac{2\pi \varepsilon}{\hbar \omega_c} \right) \cos \left( \frac{2\pi \Delta_Z}{\hbar \omega_c} \right) R_D,\]

(A2)

where \( g_0 = m^*/\pi \hbar^2 d = 2g_{LL}/\hbar \omega_c d \) is the average DoS at the Fermi level per two spin components, \( J_0(x) \) is the Bessel’s function, and \( R_D = \exp(-2\pi \Gamma/\hbar \omega_c) \) is the Dingle factor. The DoS at the Fermi level is found by making the substitution \( \varepsilon \to \mu \), where \( \mu \) is the chemical potential equal to Fermi energy. Introducing the magnetic quantum oscillation frequency \( \omega_c = \mu B_z/\hbar \omega_c \), we rewrite Eq. (A2) as
\[g_F/g_0 = 1 - 2J_0 \left( \frac{2\pi \Delta F_c}{B_z} \right) \cos \left( \frac{2\pi \Delta F_c}{B_z} \right) R_D.\]

(A3)

For conductivity the sum over two spin components appears only in the final expression in Eq. (B3), which contains the DoS per one spin component without factor \( \cos(2\pi m^*/m \cos \theta) \). Below we do not keep the Zeeman spin splitting \( \Delta_Z \) and the spin subscript \( s \) in the intermediate formulas, but similar to the standard calculations introduce it only in the end as an energy shift by \( \pm \Delta_Z \).

In bilayer crystals the quasi-2D electron dispersion \( (2) \) is additionally split by \( 2t_\perp (k_y) \) to the so-called “bonding” and “antibonding” states. The corresponding DoS for one spin component is given by the sum of contributions from the bonding and antibonding branches of electron dispersion
\[g_F/g_0 = \sum_{n=0}^{\infty} \sum_{s=\pm 1} \frac{g_{LL}/\pi}{\sqrt{4t_z^2 - (\varepsilon - s \Delta_Z - \hbar \omega_c (n + 1/2) + i \Gamma)^2}}.\]

(A4)

Applying the Poisson summation formula and keeping only the zeroth and first harmonics, similar to Eq. (A2), one obtains:
\[g_F/g_0 = 1 - \sum_{i=\pm 1} 2J_0 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) \cos \left( \frac{2\pi \varepsilon - it_z}{\hbar \omega_c} \right) R_D,\]

(A5)

which gives the DoS on the Fermi level \( \varepsilon = \mu \), corresponding to Eq. (B4).
\[g_F/g_0 = 1 - \sum_{i=\pm 1} 2J_0 \left( \frac{2\pi \Delta F_c}{B_z} \right) \cos \left( \frac{2\pi \Delta F_c}{B_z} \right) R_D.\]

(A6)

The diffusion coefficient \( D_i \) depends on its direction \( i \) with respect to magnetic field and to the crystal axes, and its oscillations can be approximated by
\[\frac{D_i}{D_0} \approx 1 - B_i J_0 \left( \frac{2\pi \Delta F_c}{B_z} \right) \sum_{l=\pm 1} \cos \left( \frac{2\pi \Delta F_c}{B_z} \right) R_D,\]

(A7)

where \( D_0 \) is the average non-oscillating part of diffusion coefficient and the coefficients \( B_i \sim 1 \) depend on the direction \( i \). For \( i \parallel z \) and without bilayer spliting it was calculated in Refs. 51-52, where in addition to \( J_0 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) \) the terms containing \( J_1 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) \) appear, which only introduce the phase shift of beats and of slow oscillations. For \( i \perp z \) these \( J_1 \left( \frac{4\pi t_z}{\hbar \omega_c} \right) \) terms are small by a factor \( \sim t_z/E_F l_0 \) and Eq. (A7) is valid.

Appendix B: Combinatorical explanation of the observed 3-peak structure of MQO

The observed 3-peak structure of MQO Fourier transform, with the central peak at least twice larger than the side peaks, can be obtained from simple combinatorics without using the Bessel’s functions. The combination of double bilayer splitting by \( t_\perp (k_y) \) and the Fermi-surface warping due to \( t_z \) with two extremal FS cross-section areas gives a four-fold splitting of MQO frequency \( F \) corresponding to the true FS pocket area both for the DoS \( g_F \) and for the diffusion coefficient \( D_i \) to oscillate with varying of magnetic field \( B_z \) perpendicular to the conducting \( x-y \) layers as:
\[\frac{g_F}{g_0} = 1 + A \sum_{j,l=\pm 1} \cos \left( \frac{2\pi F_\beta + j \Delta F_\perp + l \Delta F_\parallel}{B_z} \right) ,\]

(B1)

and
\[\frac{D_i}{D_0} \approx 1 + B_i \sum_{j,l=\pm 1} \cos \left( \frac{2\pi F_\beta + j \Delta F_\perp + l \Delta F_\parallel}{B_z} \right) .\]

(B2)
The product of Eqs. (B1) and (B2) gives

$$\frac{\sigma_i}{\sigma_i^{(0)}} = 1 + (A + B_i) \sum_{j,l=\pm 1} \cos \left( \frac{2\pi F_\beta + j \Delta F_{\perp} + l \Delta F_{\parallel}}{B_z} \right)$$

$$+ A_{\beta} B_i \sum_{j,l,j',l'=\pm 1} \cos \left( \frac{2\pi F_\beta + j \Delta F_{\perp} + l \Delta F_{\parallel}}{B_z} \right) \times \cos \left( \frac{2\pi F_\beta + j' \Delta F_{\perp} + l' \Delta F_{\parallel}}{B_z} \right),$$

(B3)

where $\sigma_i^{(0)} = e^2 g_0 D_0 l$ does not oscillate. The second term in Eq. (B3) gives the first harmonic of MQO with amplitudes $\sim A$ and four close frequencies $F_\beta \pm \Delta F_{\perp} \pm \Delta F_{\parallel} \sim F_\beta \gg \Delta F_{\perp}$, corresponding to one splitpped FS pocket. The last term in Eq. (B3) is of the second order in the amplitude $A_\beta$ and gives various frequencies: (i) for $j' = l' = 1$ the 4 second harmonics $2 \left( F_\beta \pm \Delta F_{\perp} \pm \Delta F_{\parallel} \right)$, which are strongly damped by temperature and disorder and can be neglected; (ii) for $j' = 1$ and $l' = -1$ the SIO with ultra-low frequency $2 \Delta F_{\perp} \ll \Delta F_{\parallel} \ll F_\beta$, corresponding to the very low frequency $\sim 100 T$ recently observed in YBCO; (iii) for $j' = -1$ and $l' = 1$ the SIO with intermediate frequencies $2 \Delta F_{\perp} \pm 2 \Delta F_{\parallel}$, which correspond to the observed $F_\alpha \approx 530 T$ and $F_\perp \approx F_\parallel$, $\Delta F_{\parallel}$ frequencies in YBCO. Indeed, using the identity $2 \cos x \cos y = \cos (x-y) + \cos (x+y)$ and neglecting the high frequency ($2 F_\beta$) contributions $\cos (x+y)$ we can rewrite the last term in Eq. (B3) for $j' = -1$ as

$$A_{\beta} B_i \left[ \frac{2 \cos \left( \frac{4\pi F_{\perp}}{B_z} \right)}{B_z} + \sum_{l=\pm 1} \cos \left( \frac{4\pi \Delta F_{\parallel} + l \Delta F_{\parallel}}{B_z} \right) \right].$$

(B4)

The first term in the square brackets, corresponding to $l' = 1$, gives the central peak, while the last term, corresponding to $l' = -1$, gives two side peaks. The amplitude of the central peak is doubled because there are four different combinations of $j,l$ giving this term: any $j$ and $l$ at $l' = 1$. On contrary, each side peak is given by only two combinations of $j,l$ at $l' = -1$: $j = l$ for the right side peak, and $j = -l$ for the left side peak. This combinatoric analysis was proposed in Ref. 59.

### Appendix C: Possible appearance of slow oscillations in magnetization

Similarly one can explain the fact that the slow oscillations with frequency $F_\alpha \approx 530 T$ are observed also in dHvA effect, which again contradicts the simple model above and that of Refs. 30, 35. If the electron-electron interaction is included, its effects are roughly proportional to the product of the oscillating density of states (DoS), and it should produce a nonlinearity in the magnetic oscillations of magnetization (or of other thermodynamic quantities) as a functional of the density of states. This nonlinearity results in slow oscillations of thermodynamic quantities such as magnetization, similar to those of the magneto-resistance.

Slow oscillations originate from mixing of different but close fundamental frequencies of magnetic oscillations. This mixing requires some nonlinearity. Transport properties naturally contain such nonlinearity, because they are determined by the density of states and diffusion coefficients. However, the thermodynamic potential

$$\Omega(\mu, B) = -k_B T \int d\varepsilon \rho(\varepsilon, B) \ln \left( 1 + \exp \frac{\mu - \varepsilon}{k_B T} \right),$$

(C1)

is a linear functional of the density of states (DoS $\rho(\varepsilon, B)$). Hence, thermodynamic quantities, e.g. magnetization $M = -\partial \Omega(\mu, B)/\partial B$, are also linear functionals of the density of states (DoS) $\rho(\varepsilon, B)$ Hence, for slow oscillations to take place in magnetization, the non-linearity must appear already in the DoS $\rho(\varepsilon, B)$. The DoS is related to the imaginary part of the retarded Green’s function $G_R(\eta, \varepsilon)$ as $\rho(\varepsilon, B) = -\sum_\eta \text{Im} G_R(\eta, \varepsilon)/\pi$, where $\eta = \{n, k_y, k_z\}$ is a set of quantum numbers of quasiparticles in magnetic field. This Green’s function $G_R(\eta, \varepsilon)$ includes all relevant types of interaction: with impurities, electron-phonon and electron-electron, which are contained in the self-energy part $\Sigma_B \equiv \Sigma_R(\eta, \varepsilon, B)$: $G_R(\eta, \varepsilon) = [\varepsilon - \epsilon(\eta, B) - \Sigma_B]^{-1}$, where $\epsilon(\eta, B)$ is the bare energy spectrum in the presence of magnetic field. Hence, the DoS

$$\rho(\varepsilon, B) = \sum_\eta \frac{-\text{Im} \Sigma_R(\eta, \varepsilon, B)/\pi}{[\varepsilon - \epsilon(\eta, B) - \text{Re} \Sigma_R(\eta, \varepsilon, B)]^2 + [\text{Im} \Sigma_R(\eta, \varepsilon, B)]^2}. \quad (C2)$$

If the self-energy part $\Sigma(\eta, \varepsilon, B)$ is independent of $\eta$, the sum over $\eta$ in Eq. (C2) can be calculated analytically. In quasi-2D metals $\epsilon(\eta, B) = \hbar \omega_c (n + \gamma) + 2t_z \cos (k_z d)$, and applying the Poisson summation formula one obtains

$$\rho(\varepsilon, B) \rho_0 = 1 + 2 \sum_{k=1}^\infty (\varepsilon^2 - 1)^k J_0 \left( \frac{4 \pi k t_y}{\hbar \omega_c} \right) \exp \left( -2\pi k \frac{\text{Im} \Sigma_R(\varepsilon, B)}{\hbar \omega_c} \right) \cos \left( 2\pi k \frac{\varepsilon - \text{Re} \Sigma_R(\varepsilon, B)}{\hbar \omega_c} \right). \quad (C3)$$
The non-linearity of the oscillating field dependence is clearly seen from this expression. Naively, one would expect that already the impurity scattering, which in the Born approximation gives oscillating \( \Im \Sigma_R(\varepsilon, B) \propto \rho(\varepsilon, B) \), results to slow oscillations of \( \rho(\varepsilon, B) \). However, this is not the case, because, as first shown in Ref.\(^{30}\), in the lowest (second) order of the Dingle factor \( \exp(-2\pi |\Im \Sigma_R(\varepsilon, B)|/\hbar \omega_c) \), the contribution from \( \Re \Sigma_R \) exactly cancels the contribution from \( \Im \Sigma_R \).

Thus, to the slow oscillations of magnetization. Therefore, in organic metals, which are rather good clean metals, the slow oscillations of magnetization were not observed.\(^{31}\) However, in cuprates, where e-e interaction is very strong and the impurity concentration is very high, the slow oscillations of magnetization should appear.

Doping changes the size of unreconstructed Fermi-surface considerably, giving a very large relative change of the size of any small reconstructed Fermi-surface pockets.

In conclusion, we find that the effective parameter coming from the temperature dependence of the square of Dingle temperature (see Sec.IIC). An excellent fit of experimental data by the temperature damping factor $R_T$ of the Lifshitz-Kosevich formula has been achieved (see Fig. 6c in Ref.2), at least for one doping level $p \approx 0.108$ over a wide temperature interval $1K < T < 16K$. Such a good fit is atypical even for materials which are much cleaner and have stoichiometric chemical composition and almost ideal crystal structure. In any case, the temperature-dependent Dingle factor due to e-e interactions in YBCO should spoil the ideal dependence $R_T(T)$, which in Fig. 6c in Ref.2 survived even up to $T = 16K$. Therefore, we believe that the quality of the fit may be accidental.

The electron level broadening $\Gamma$ is related to the Dingle temperature $T_D = \Gamma/k_B$ and to the effective electron mean free time $\tau = \hbar/2\Gamma$. Usually, at low temperatures one takes into account only electron scattering by impurities, which gives a temperature-independent Dingle factor. The contribution to $T_D$ from electron-electron ($e-e$) and electron-phonon ($e-ph$) increases with temperature and may be confused with the damping factor coming from temperature $R_T$, thus leading to the incorrect estimate of the effective mass from the oscillations. While in the lowest order of perturbation theory the electron-phonon contributions to $T_D$ and to $m^*$ were shown to compensate each other, the electron-electron contribution to $T_D$ in disordered metals needs further theoretical study.
For simplicity we assume the chemical potential $\mu$ to be constant. In the opposite limit of constant particle density the chemical potential is an oscillating function of magnetic field, which gives additional nonlinearity to the functional $M[\rho(\varepsilon, B)]$.
