(Dated: June 12, 2023)

ARPES studies of the protected surface states in the Topological Insulator $Bi_2Te_3$ have revealed the existence of an important hexagonal warping term in its electronic band structure. This term distorts the shape of the Dirac cone from a circle at low energies to a snowflake shape at higher energies. We show that this implies important modifications of the interband optical transitions which no longer provide a constant universal background as seen in graphene. Rather the conductivity shows a quasilinear increase with a slightly concave upward bending as energy is increased. Its slope increases with increasing magnitude of the hexagonal distortion as does the magnitude of the jump at the interband onset. The energy dependence of the density of states is also modified and deviates downward from linear with increasing energy.

I. INTRODUCTION

Topological Insulators are insulating in the bulk and have symmetry protected helical Dirac fermions on their surface with an odd number of Dirac points in the surface state Brillouin zone. The surface charge carriers are massless and relativistic with linear in momentum energy dispersion curves. Spin sensitive angular resolved photo emission spectroscopy (ARPES) also shows that their spins are locked to their momentum. The position of the chemical potential relative to the Dirac point and the gapped bulk bands is not as easily tuned as it is in graphene but can be controlled by doping with Sn in $(Bi_{1–δ}Sn_{δ})_2Te_3$ or with Ca in $Bi_{2–δ}Ca_{δ}Te_3$ with further dosing with NO$_2$ molecules. The constant energy contours in $Bi_2Te_3$ as measured by ARPES are not circles as they are in graphene but have an hexagonal distortion which gives them snowflake shape. This geometry was modeled by Fu [11] with an unconventional hexagonal warping term in the bare band Hamiltonian of $Bi_2Te_3$ with parameters fit to the measured Fermi surface.

Optical spectroscopy has been a very powerful method to obtain valuable information on the charge dynamics of the Dirac fermions in graphene. An experimental review was given by Orlita and Potemski. Usually it is the zero momentum q limit of the optical conductivity as a function of photon energy which is measured but very recently finite q’s have also been measured using near field techniques. Optics has also been used to study topological insulators. In this paper we study how hexagonal warping in $Bi_2Te_3$ manifest in the optical conductivity, which we find is profoundly modified for the parameters determined in the work of Fu [11].

II. FORMALISM

The Hamiltonian used by Fu [11] to describe the surface states band structure near the Γ point in the surface Brillouin zone is

$$H_0 = v_F(k_x\sigma_y - k_y\sigma_x) + \frac{\lambda}{2}(k_x^2 + k_y^2)\sigma_z + E_0(k)$$  \hspace{1cm} (1)$$

where $E_0(k) = \hbar^2k^2/(2m^*)$ is a quadratic term which gives the Dirac fermionic dispersion curves an hour glass shape and provides particle-hole asymmetry. The Dirac fermion velocity to second order is $v_F = v_F(1 + \alpha k^2)$ with $v_F$ the usual Fermi velocity measured to be 2.55 eV ⋅ Å and $\alpha$ is a constant which is fit along with $m^*$ to the measured band structure in the reference [11]. The hexagonal warping parameter $\lambda = 250$ eV ⋅ Å$^3$. The $\sigma_x$, $\sigma_y$, $\sigma_z$ are the Pauli matrices here referring to spin, while in graphene these would relate to pseudospin instead. Finally $k_x = k_x \pm ik_y$ with $k_x$, $k_y$ momentum along $x$ and $y$ axis respectively. The energy spectrum associated with the Hamiltonian [Eq. (1)] is

$$E_z(k) = E_0(k) ± \sqrt{v_F^2k^2 + \lambda^2k^6\cos^2(\theta)}$$  \hspace{1cm} (2)$$

where $\theta$ is the polar angle defining the direction of $k$ in the two dimensional surface state Brillouin zone. The energy dispersion curves in Eq. (2) reduce to the well known linear law $±vk$ of graphene when $E_0$ is set zero along with $\lambda = 0$, i.e. ignoring hexagonal warping. Since our primary interest here is getting a first understanding of how the warping term in Eq. (2) manifests itself in the dynamical conductivity of the surface helical Dirac fermions we will for simplicity from here on drop the $E_0(k)$ term which as we have said provides particle-hole asymmetry.

In FIG. we show a color plot for the constant energy contour associated with the dispersion curves [Eq. (2)] as the energy is increased above that of the Dirac point.

* lizhou@univmail.cis.mcmaster.ca
In strained graphene we would have elliptical contours instead of circle. In graphene we would have circles for all energies and which is achieved when \( \delta = 67\% \) corresponds to a chemical potential of 250 meV. The kx and ky axes are in the units of 0.1 \( \AA^{-1} \). Also shown is the surface state Brillouin zone identifying \( \Gamma, K \) and \( M \) points.

The contour changes shape and shows greater hexagonal distortion displaying a snowflake shape. The largest flake shown corresponds to a chemical potential of 250 meV which is achieved when \( \delta = 0.67\% \) in \((Bi_{1-\delta}Sn_{\delta})_2Te_3\). In graphene we would have circles for all energies and in strained graphene we would have elliptical contours instead of circle.

The Kubo formula for the \( xx \) component of the dynamic conductivity \( \sigma_{xx}(\omega) \) as a function of photon energy \( \omega \) is given in terms of the matrix Matsubara Green’s function \( G(k, \omega_n) \) with \( \omega_n \) the Fermionic Matsubara imaginary frequency as

\[
\sigma_{xx}(\omega) = -\frac{e^2}{i\omega} \frac{1}{4\pi^2} \int_{k_{\text{cut}}} \frac{kdkd\theta}{T} \sum_l \text{Tr} (v_x \tilde{G}(k, \omega_l) v_x \tilde{G}(k, \omega_n + \omega_l))_{i\omega_n \rightarrow \omega + i\delta}
\]  

(3)

with \( e \) the charge on the electron, \( k \) the absolute value of the momentum with direction \( \theta \) and \( k_{\text{cut}} \) a cut-off. Here \( T \) is the temperature with \( \omega_n = (2n + 1)\pi T \) and \( \omega_l = 2l\pi T \) the Fermion and Boson Matsubara frequencies. \( n \) and \( l \) are integers and \( \text{Tr} \) is a trace. To get the conductivity which is a real frequency quantity, we needed to make an analytic continuation from imaginary \( i\omega_n \) to real \( \omega \) and \( \delta \) is infinitesimal. As written we have neglected vertex correction and so the factors \( v_x \) are simply the velocity components given by

\[
v_x = v_k \sigma_y + 3 \lambda k^2 \cos(2\theta) \sigma_z
\]

(4)

\[
v_y = -v_k \sigma_x - 3 \lambda k^2 \sin(2\theta) \sigma_z
\]

(5)

obtained directly from the Hamiltonian [Eq. (1)]. We have set all \( \hbar \) factors equal to one.

The matrix Green’s function for the non-interacting bare band is given by

\[
\hat{G}_0(k, i\omega_n) = \frac{1}{i\omega_n + \mu - v_k (k_x \sigma_y - k_y \sigma_x) - \frac{1}{2} (k_x^2 + k_y^2) \sigma_z}
\]

\[
= \frac{i\omega_n + \mu + v_k (k_x \sigma_y - k_y \sigma_x) + \lambda k^3 \cos(3\theta) \sigma_z}{(i\omega_n + \mu)^2 - v_k^2 k^2 - \lambda^2 k^6 \cos^2(3\theta)}
\]

(6)

with

\[
(k_x^3 + k_y^3)^2 = (2k_x^3 - 6k_x k_y^2)^2 = 4k^6 \cos^2(3\theta)
\]

(7)

It is convenient to rewrite the \( \hat{G}_0(k, i\omega_n) \) in terms of \( \hat{G}_0(k, s, i\omega_n) \) defined as

\[
\hat{G}_0(k, s, i\omega_n) = \frac{1}{i\omega_n + \mu - s \sqrt{v_k^2 k^2 + \lambda^2 k^6 \cos^2(3\theta)}}
\]

(8)

where \( s = \pm 1 \) and \( \mathbf{F}_k \) defined as

\[
\mathbf{F}_k = \frac{(-v_k k \sin \theta, v_k k \cos \theta, \lambda k^3 \cos(3\theta))}{\sqrt{v_k^2 k^2 + \lambda^2 k^6 \cos^2(3\theta)}}
\]

(9)

This gives

\[
\hat{G}_0(k, i\omega_n) = \frac{1}{2} \sum_{s=\pm} (1 + s \mathbf{F}_k \cdot \sigma) \hat{G}_0(k, s, i\omega_n)
\]

(10)
III. SIMPLIFICATION OF EXPRESSION FOR $\sigma_{xx}(\omega)$

We will be interested here only with the interband terms in which case the required trace gives

$$
Tr\langle v_x \hat{G}(k, \omega) v_x \hat{G}(k, \omega_I + \omega_n) \rangle / H(\theta) = \frac{1}{i\omega_n + \mu - E_-} \frac{1}{i\omega_n + \mu - E_+} + \frac{1}{i\omega_n + \mu - E_+} \frac{1}{i\omega_n + \mu - E_-}.
$$

(11)

where

$$
H(\theta) = \lambda^2 k^6 (\cos^2(3\theta) - 2 \times 3 \cos \theta \cos(2\theta) \cos(3\theta) + 9 \cos^2(2\theta)) + v_F^2 k^2 \sin^2 \theta
$$

(12)

But we know that

$$
T \sum_i \frac{1}{i\omega_i + \mu - E_-} \frac{1}{i\omega_i + \mu + E_+} + \frac{1}{i\omega_i + \mu + E_+} \frac{1}{i\omega_i + \mu - E_-} = \frac{f(E_-) - f(E_+)}{i\omega_n - E_+ + E_+} + \frac{f(E_+) - f(E_-)}{i\omega_n - E_+ + E_-}.
$$

(13)

and hence we obtain

$$
\sigma_{xx}(\omega) = \frac{e^2}{i\omega} \frac{1}{4\pi^2} \int_0^{k_{cut}} kd k d\theta \frac{H(\theta)}{(v_F^2 k^2 + \lambda^2 k^6 \cos^2(3\theta))} \left[ \frac{f(E_-) - f(E_+)}{i\omega_n - E_+ + E_+} + \frac{f(E_+) - f(E_-)}{i\omega_n - E_+ + E_-} \right] \omega_n + i\delta
$$

(14)

Here $f(x)$ is the Fermi-Dirac distribution function given by $f(x) = 1 / [\exp(x/T - \mu/T) + 1]$, where we have ignored the Boltzmann constant $k_B$ but will include it in the calculation. We have verified that $\sigma_{xx}(\omega) = \sigma_{xx}(\omega)$, after an analytic continuation from imaginary to real Matsubara frequencies we obtain the final expression

$$
\sigma_{xx}(\omega) = \frac{e^2}{i\omega} \frac{1}{4\pi^2} \int_0^{k_{cut}} kd k d\theta \frac{H(\theta)}{W(k, \theta)} \times \left[ \frac{f(E_-) - f(E_+)}{\omega - 2\sqrt{W(k, \theta) + i\delta}} + \frac{f(E_+) - f(E_-)}{\omega + 2\sqrt{W(k, \theta) + i\delta}} \right]
$$

(15)

where $W(k, \theta) = v_F^2 k^2 + \lambda^2 k^6 \cos^2(3\theta)$.

IV. ANALYTIC FORM FOR THE REAL PART OF CONDUCTIVITY

The real part of the dynamic conductivity which is the absorptive part can be simplified further using the usual rule $\frac{1}{\omega + i\delta} = \frac{\delta}{\omega} - i\pi \delta(\omega)$. From Eq. (15) we get

$$
Re \sigma_{xx}(\omega) = -\frac{e^2}{\omega} \frac{1}{4\pi^2} \int_0^{k_{cut}} kd k d\theta H(\theta) \times \frac{[f(E_-) - f(E_+)]}{W(k, \theta)} (-\pi) \delta(\omega - 2\sqrt{W(k, \theta)})
$$

(16)

which can be rewritten as

$$
Re \sigma_{xx}(\omega) = \frac{e^2}{2\omega} \frac{1}{4\pi} \int_0^{k_{cut}} d(k^2) d\theta H(\theta) \times \frac{[f(-\omega/2) - f(\omega/2)]\delta(\omega - 2\sqrt{W(k, \theta)})}{W(k, \theta)}
$$

(17)

and we get

$$
Re \sigma_{xx}(\omega) = \frac{e^2 [f(-\omega/2) - f(\omega/2)]}{24\pi \omega^2} \times \int_0^{k_{cut}} \frac{d(k^2) d\theta}{|\lambda^2 k^6 \cos(3\theta k, \omega) \sin(3\theta k, \omega)|}
$$

(18)

where the thermal factor $f(\omega)$ have been pulled out of the integral over momentum. The Dirac delta function has been used in the process. We wrote

$$
\delta(\omega - 2\sqrt{W(k, \theta)}) = \omega \delta(\theta - \theta_{k, \omega})
$$

(19)

where

$$
\theta_{k, \omega} = \pm \frac{1}{3} \arccos[\pm \sqrt{\frac{\omega^2/4 - v_F^2 k^2}{\lambda^2 k^6}}],
$$

$$
\pm \frac{1}{3} \{ \arccos[\pm \sqrt{\frac{\omega^2/4 - v_F^2 k^2}{\lambda^2 k^6}}] + \pi \},
$$

$$
\pm \frac{1}{3} \{ \arccos[\pm \sqrt{\frac{\omega^2/4 - v_F^2 k^2}{\lambda^2 k^6}}] + 2\pi \}.
$$

(20)

This is our final expression for the absorptive part of the conductivity. Numerical results based on this expression are given in the next section. Before doing so however we present a similar expression for the density of states $D(\omega)$ as a function of energy which could be measured in scanning tunneling microscopy (STM). By its definition

$$
D(\omega) = -\frac{1}{\pi} \sum_k Im Tr \hat{G}(k, \omega_n - \omega + i\delta)
$$

(21)

which can be reduced to

$$
D(\omega) = -\frac{1}{\pi} \frac{1}{4\pi^2} \int_0^{k_{cut}} kd k d\theta Im \left[ \frac{1}{\omega - \sqrt{W(k, \theta) + i\delta}} + \frac{1}{\omega + \sqrt{W(k, \theta) + i\delta}} \right]
$$

(22)

Taking the imaginary part gives

$$
D(\omega) = \frac{1}{4\pi^2} \int_0^{k_{cut}} kd k d\theta \delta(\omega - \sqrt{W(k, \theta)}) \Theta(\omega)
$$

(23)
FIG. 2. (Color online) The real part of the optical conductivity $\sigma_{xx}(\omega)$ as a function of photon energy $\omega$ in meV (in units of $2\pi e^2/h$) for a case which corresponds approximately to $\delta = 0.67\%$ Sn doping with chemical potential $\mu = 0.25eV$. We show 4 values of $\mu$. In all cases finite $\mu$ transfers optical spectral weight from the interband transitions to the intraband. These, not shown here, provide a Drude like contribution at $\omega$ near zero.

which works out to

$$D(\omega) = \frac{\omega}{12\pi^2\lambda^2} \int_0^{k_{\text{cut}}} \frac{kdk}{[k^6 \cos(3\theta_{k,\omega}) \sin(3\theta'_{k,\omega})]} \Theta(\omega)$$

$$+ (\omega \to -\omega)$$

(24)

where $\Theta(\omega)$ is the Heaviside step function and we have used

$$\delta(\omega - \sqrt{W(k, \theta)}) = \frac{\omega\delta(\theta - \theta'_{k,\omega})}{[3\lambda^2k^6 \cos(3\theta'_{k,\omega}) \sin(3\theta'_{k,\omega})]}$$

(25)

where $\theta'_{k,\omega}$ can be obtained from Eq. (20) by replacing $\omega$ with $2\omega$ so we have $\theta'_{k,2\omega} = \theta_{k,\omega}$.

V. NUMERICAL RESULTS

In FIG. 2 we show our results for the real part of the optical conductivity $Re\sigma_{xx}(\omega)$, in units of $2\pi e^2/h$, as a function of photon energy $\omega$ for a $Bi_2Te_3$ doped with Sn at level $\delta = 0.67\%$ (see references 6 and 11) which corresponds to a chemical potential $\mu = 250meV$ and all other parameters determined in the fit by Fu. 11 We show four values of $\mu$. In all cases the threshold for the start of the interband transitions is sharp and occurs at $\omega = 2\mu$, as it would in graphene. The missing optical spectral weight in the interband transition is accompanied with an increase in the intraband (Drude) optical spectral weight. This is not shown in our picture. Because we have not included any scattering processes in our work, the Drude manifests as a Dirac delta function at $\omega = 0$ and does not overlap with the interband contribution which we emphasize here. At small values of $\omega$, the value of $Re\sigma(\omega)$ is rather flat and takes on precisely the value expected for graphene without the degeneracy factor $g = 4$, which counts spin and valley degrees of freedom. For a topological insulator there is only one Dirac cone and spin is no longer degenerate. We also note that the background value is independent of material parameters such as the Fermi velocity. But this is no longer the case for a topological insulator. As $\omega$ is increased whatever the value of $\mu$ the conductivity increases rather rapidly above its universal background value and shows concave upward behavior. This is traced to the changes in fermi velocity of Eq. 4 and Eq. 5 due to the warping term proportional to $\lambda$ and to the change in quasiparticle band structure. In FIG. 3 we show how $Re\sigma(\omega)$ v.s. $\omega$ is changed as $\lambda$ is changed. Here and also in FIG. 3 the $\lambda$ has been multiplied by the cube of the typical Fermi
As $\lambda$ is increased however $D(\omega)$ starts to deviate from linearity and, as we see in FIG. 4, is progressively reduced below the solid black curve. This is easily understood with the help of the right inset where we plot the constant energy contours for $\omega = \mu = 0.25eV$ for the three value of $\lambda$ considered. For $\lambda = 0$ we get the black circle of graphene theory. As $\lambda$ increases this contour distorts into a snowflake pattern (blue curve) which is however completely contained inside the black circle. Of course, to keep the number of charge carriers the same we need to increase the chemical potential with increasing value of the warping parameter $\lambda$ as we show in the left inset. What is plotted is the value of $\lambda$ at fixed value of the number of charge carriers, which is around $1.1 \times 10^{16}/m^2$.

VI. SUMMARY AND CONCLUSION

Helical Dirac fermions exist at the surface of a topological insulator (TI). These charge carriers have some similarity and also differences with the well known chiral Dirac fermions in graphene. An important difference is a degeneracy factor $g$ of four which comes from the valley and spin degrees of freedom of graphene not applicable in TI. Another important difference, well investigated in the case of $Bi_2Te_3$ doped with $Sn$, is the hexagonal distortion seen in ARPES. Here we have studied how such a term changes optical properties. For realistic values of the warping parameter we found large changes in the interband transitions.

A third difference is that, graphene involves pseudospin related to the sublattice degeneracy in its two atoms per unit cell crystal structure rather than real spin. Furthermore in graphene the bands are spin degenerate, while in a topological insulator momentum and spin are locked with $x$-$y$ component of real spin oriented perpendicular to its 2-D momentum $k$, with clockwise and anticlockwise orientation in conduction and valence band respectively.

The universal flat background observed in graphene remains at small photon energies although modified by a factor of 4 because the valley spin degeneracy no longer applies. As $\omega$ increases large modifications in the effect of the interband transitions on the conductivity are noted, and these encode the information on the hexagonal warping of the Dirac cone cross-section leading to a snowflake pattern. Instead of being flat $Re\sigma(\omega)$ increases in a quasilinear fashion with a concave upward bent. The magnitude of this linear increase becomes larger with the magnitude of the hexagonal warping term as does the value of the jump in the conductivity at the threshold of twice the chemical potential ($\omega = 2\mu$). At the same time, we find that the density of state remains linear only at small $\omega$ and starts to fall below this linear behavior at the energy where the conductivity also starts to show its deviation from a constant background value. While the conductivity curves are bent upward due to fermi velocity features, the density of state bends downward a prediction that could be verified in combined optics and
scanning tunneling spectroscopy (STS) experiment.
