Melting as a String-Mediated Phase Transition

Leonid Burakovsky, Dean L. Preston, and Richard R. Silbar

Abstract

We present a theory of the melting of elemental solids as a dislocation-mediated phase transition. We model dislocations near melt as non-interacting closed strings on a lattice. In this framework we derive simple expressions for the melting temperature and latent heat of fusion that depend on the dislocation density at melt. We use experimental data for more than half the elements in the Periodic Table to determine the dislocation density from both relations. Melting temperatures yield a dislocation density of $(0.61 \pm 0.20) \, b^{-2}$, in good agreement with the density obtained from latent heats, $(0.66 \pm 0.11) \, b^{-2}$, where $b$ is the length of the smallest perfect-dislocation Burgers vector. Melting corresponds to the situation where, on average, half of the atoms are within a dislocation core.

Key words: melting, dislocation, phase transition, lattice

1 Introduction

Nearly 50 years ago Shockley successfully accounted for the fluidity of a liquid by assuming a certain concentration of line defects in the liquid state. Bragg had earlier estimated an upper bound on the core energy of a dislocation under the assumption
that the core atomic configuration was like that of a liquid. Cotterill and Doyama \cite{cotterill1968}
later confirmed the Bragg estimate. These early results implied that the liquid state is
equivalent to a crystal saturated with dislocation cores. It was first suggested by Mott \cite{mott1935}
that the melting transition could be described in terms of dislocations.

There are now compelling results from molecular dynamics \cite{mackintosh2001} and Monte Carlo \cite{mackintosh2001}
simulations that imply that dislocations play a key role in three-dimensional melting, and
moreover there is experimental evidence that linear defects are in fact generated near the
melting transition \cite{benvenuti2010}.

Mizushima \cite{mizushima1970} and Ookawa \cite{ookawa1971} were the first to formulate a dislocation theory of melting.
They based their theory on the fact that the self-energy of a dislocation decreases
with dislocation density because of screening. In their theory melting is a first-order
transition that occurs when the free energy of the crystal with a sufficiently high concentra-
tion of thermally-generated dislocations equals the free energy of the dislocation-free
crystal. Their predicted melting temperatures agree with data for reasonable choices of
the core energy. Many dislocation theories of melting then followed \cite{kleinert1996-1, kleinert1996-2, kleinert1996-3, kleinert1996-4},
most notably the exhaustive treatment of linear-defect-mediated melting by Kleinert and collaborators
\cite{kleinert1996-5}. We refer the reader to several fine reviews of the literature for additional details and
references on dislocation-mediated melting \cite{kleinert1996-6, kleinert1996-7}.

Significant progress in our understanding of melting has been achieved by Kleinert
\cite{kleinert1996-5} who pointed out that the melting process cannot proceed through the mediation of
dislocations alone. Dislocations are associated with the discrete translational symmetry of
the crystal, so only this symmetry is lost when dislocations condense. But the rotational
order of the solid is also lost as the solid converts into liquid, and for this to occur the
defects associated with the rotational symmetry of the lattice, namely disclinations, must
come into play. Kleinert assumes that the free energy of dislocations alone would lead to
a second-order phase transition, and in addition shows that a second-order proliferation
of disclinations can occur in a background of dislocations above some critical density. The
coupled dislocation-disclination system could, however, undergo a first-order transition,
i.e., melting.

Although disclinations must participate in the melting process, in this paper we con-
sider only the dislocation degrees of freedom. Ideally, we would derive the precise form of
the free energy of a dense ensemble of dislocations interacting via the full Blin potential
\cite{kleinert1996-5} and subject to specific configurational constraints (Brownian, self-avoiding, etc.), but
this problem has so far defied solution. Instead we develop an effective theory of melting
based on perfectly screened, non-interacting dislocations. We employ the widely accepted
$-\rho \ln \rho$ form ($\rho$ is dislocation density) for the self-energy density of dislocations \cite{kleinert1996-8, kleinert1996-9, kleinert1996-10},
which results in a first-order phase transition. A dislocation in a dense ensemble of other
dislocations is assumed to be a random loop, i.e., the possible configurations of a disloca-
tion loop are closed random walks, and short-range steric interactions are neglected. Thus
the partition function is evaluated in the independent-loop approximation. We obtain two
new relations: a simple expression for the melting temperature (the melting relation) that
explicitly takes into account the crystal structure, and another relation between melting
temperature, latent heat of fusion, and critical density of dislocations. We carry out a
comprehensive comparison of these relations with experimental data on over half of the
Periodic Table. The melting relation is accurate to 17% \cite{19}. Dislocation densities as determined from the melting temperature and latent heat relations are \( \rho = (0.61 \pm 0.20) b^{-2} \) and \( (0.66 \pm 0.11) b^{-2} \), respectively, where \( b \) is the length of the smallest perfect-dislocation Burgers vector. Both relations should also apply to alloys and compounds.

In Section 2 we discuss the statistical mechanics of dislocation loops on a lattice. These results are used to derive the melting relation in Section 3, the free energy density in Section 4, and the formula for the latent heat of fusion in Section 5. The values for the critical dislocation density extracted from both the melting relation and the formula for the latent heat of fusion are checked in Section 6 with the formula for volume change at melt. Our concluding remarks appear in Section 7.

2 Statistical mechanics of dislocation loops on a lattice

The energy per unit length, \( \sigma \), of a dislocation can be very large. However, this energy can always be compensated at sufficiently high temperatures by the large entropy of line-like structures, as will be seen in what follows.

In a Bravais lattice with coordination number \( z \) we consider the graph \( \Gamma \), the edges of which are all nearest-neighbor links. The set of \( z \) links from any lattice site is identical to the set of shortest perfect-dislocation Burgers vectors, of length \( b \). We now evaluate the partition function for a single Brownian loop on \( \Gamma \).

The line tension, \( \sigma \), is assumed to be independent of its length, \( L \), as is the case for a dislocation in a dense complex network. (In a dilute network, interactions between distant segments of a dislocation lead to a logarithmic dependence of \( \sigma \) on \( L \).) The number of configurations of a string of length \( L \) is \( (z')^{L/b} \), where \( z' \) is the number of possible directions that a line segment can take from a given lattice site. If backtracking is not allowed, \( z' = z - 1 \). For a simple cubic lattice in \( D \) dimensions \( z = 2D \).

Hence, the partition function for a single closed dislocation (in 3 dimensions) is

\[
Z_1 = \sum_L p(L, V) (z')^{L/b} e^{-\beta \sigma L} = \sum_L p(L, V) e^{-\beta \sigma_{\text{eff}} L}, \quad \sigma_{\text{eff}} \equiv \sigma \left( 1 - \frac{T \ln z'}{\sigma b} \right),
\]

where \( \beta \equiv 1/k_B T \), \( p(L, V) \) is the sum of probabilities over all lattice sites that a dislocation of length \( L \) will close, \( V \) is the volume of the system, and \( \sigma_{\text{eff}} \) is the effective energy cost to create unit length of a string at temperature \( T \).

In order to calculate \( p(L, V) \), let \( p(r', r; L/b) \) be the probability density for a dislocation of \( L/b = n \) steps to start at \( r \) and end at \( r' \). In the limit \( n \to \infty \), \( b \to 0 \), and \( L = \text{const} \), \( p(r', r; L/b) \) satisfies the diffusion equation \cite{20}

\[
\frac{\partial p}{\partial n} = \frac{b^2}{z'} \nabla^2 p,
\]

the solution of which is the heat-kernel expansion

\[
p(r', r; L/b) \equiv p(r' - r; L/b) = \sum_k f_k(r) f_k^*(r') e^{-E_k L/b},
\]
where the $f_k(r)$ are eigenfunctions of the Laplacian,

$$-\frac{b^2}{z'} \nabla^2 f_k = E_k f_k,$$

which we take as normalized according to

$$\int d^3r |f_k(r)|^2 = 1. \quad (5)$$

When $V \to \infty$, we have

$$f_k(r) = \frac{1}{\sqrt{V}} e^{ik \cdot r}, \quad E_k = \frac{b^2 k^2}{z'}, \quad (6)$$

where $0 \leq k = |k| \leq \infty$. It then follows from Eq. (3), in which we replace a sum by an integral,

$$\sum_k \to \frac{V}{(2\pi)^3} \int d^3k,$$

that

$$p(r' - r; L/b) = \int \frac{d^3k}{(2\pi)^3} e^{ik \cdot (r-r') - bLk^2/z'} = \left( \frac{z'}{4\pi bL} \right)^{3/2} e^{-z'(r'-r)^2/4bL}. \quad (7)$$

The normalization (5) of the eigenfunctions thus imparts unit normalization to the probability density:

$$\int d^3u \ p(u; L/b) = 1. \quad (8)$$

The partition function for a dislocation loop $(r' = r)$ is therefore

$$Z_1 = \sum_L \frac{b}{L} \int d^3r \ p(0; L/b)e^{-\beta \sigma_{eff} L} = \left( \frac{z'}{4\pi} \right)^{3/2} \frac{V}{b^3} \sum_L \left( \frac{L}{b} \right)^{-5/2} e^{-\beta \sigma_{eff} L} \equiv \sum_L N(L)e^{-\beta \sigma L}, \quad (9)$$

where the factor $b/L$ removes the overcounting due to the degeneracy in the number of starting points on the loop. Here, $N(L)$ is the number of configurations of a loop of length $L$. The exponent $5/2$ becomes $1 + D/2$ in $D$ dimensions [21].

Real dislocations are not necessarily Brownian loops. In fact, they are expected to be self-avoiding and/or neighbor-avoiding loops, so they do not penetrate each other’s core. Eq. (9) can then be extended to non-Brownian or open dislocations by means of an effective exponent $q + 1 \neq 5/2$ and normalization constant $A(q, z')$ [22], as follows:

$$Z_1 = A(q, z') \frac{V}{b^3} \sum_L \left( \frac{L}{b} \right)^{-q-1} e^{-\beta \sigma_{eff} L}. \quad (10)$$

Here, $q = -1$ for non-interacting (Brownian) open dislocations [22] and $q \approx 7/4$ for self-avoiding dislocations at low densities in 3 dimensions [22]. In the string literature, the value $q = 0$ has also been quoted. A general argument based on modular invariance [23] shows that for non-interacting closed strings $q = 0$ for sufficiently high energy on any compact target space. The same value of $q$ was also obtained in a discrete model for strings [24], and as a static solution to the string Boltzmann equation [25]. In principle, $q$ may even be a function of temperature. Although we may expect $3/2 \leq q \leq 7/4$ [12], our
main conclusions do not depend on the precise value of $q$. The normalization constant, $A(q, z')$, can be calculated analytically for Brownian loops in any dimension ($q = D/2$), analogously to the calculation of $A(3/2, z') = (z'/4\pi)^{3/2}$ in Eq. (9), and numerically in other cases.

The average length of a loop is

$$\langle L \rangle = \frac{\sum_L L N(L) e^{-\beta \sigma L}}{\sum_L N(L) e^{-\beta \sigma L}} = \frac{\xi(T)}{\bar{\xi}(T)} b,$$

where we define

$$\xi(T) \equiv A(q, z') \sum_{L/b} \left( \frac{L}{b} \right)^{-q} e^{-\beta \sigma_{\text{eff}} L},$$

and

$$\bar{\xi}(T) \equiv A(q, z') \sum_{L/b} \left( \frac{L}{b} \right)^{-q-1} e^{-\beta \sigma_{\text{eff}} L} = \frac{b^3}{V} Z_1.$$

The grand canonical partition function for an ensemble of non-interacting indistinguishable loops is given by

$$Z = Z(T, V, \mu) = \sum_{N=1}^{\infty} \frac{Z_1^N}{N!} e^{\mu N/k_BT} = \exp \{ \exp \left( \frac{\mu}{k_BT} \right) Z_1 \},$$

where $\mu$ is the chemical potential. The free energy of the ensemble is

$$F = -k_BT \ln Z = -k_BT e^{\mu/k_BT} Z_1.$$

The average number of loops in the ensemble is

$$\bar{N} = -\left( \frac{\partial F}{\partial \mu} \right)_{T,V} = e^{\mu/k_BT} Z_1.$$

Since $Z = \sum_{L_i} N(L_i) e^{-\beta (\sigma L_i - \mu)}$, where $N(L_i)$ is the number of dislocation configurations of total length $L_i$, the average total dislocation length in the ensemble is

$$\bar{L} = \frac{1}{Z} \sum_{L_i} L_i N(L_i) e^{-\beta (\sigma L_i - \mu)} = -\frac{\partial \ln Z}{\partial (\beta \sigma)} = -e^{\mu/k_BT} \frac{\partial Z_1}{\partial (\beta \sigma)}$$

$$= \bar{N} \frac{\sum_L LN(L) e^{-\beta \sigma L}}{\sum_L N(L) e^{-\beta \sigma L}} = \bar{N} \langle L \rangle,$$

i.e., the average total dislocation length is equal to the average number of loops times the average loop length.

The dislocation density, $\rho$, is the average total length per unit volume. It then follows from (12),(13) and (17) that

$$b^2 \rho(T) = \frac{\bar{N} \langle L \rangle}{V} b^2 = \frac{\bar{N} \xi(T)}{V \bar{\xi}(T)} b^3 = e^{\mu/k_BT} \xi(T).$$
3 New melting relation

The effective line tension, \( \sigma_{\text{eff}} \), [see Eq. (1)] vanishes at the critical temperature \( k_B T_{cr} \equiv \sigma b / \ln z' \). Consequently, dislocations proliferate as \( T_{cr} \) is approached from below. At temperatures above \( T_{cr} \), the divergence of \( Z_1 \) signals the breakdown of the underlying theory, and the system enters a new phase. Hence, the temperature \( T_{cr} \) corresponds to a phase transition, in which dislocations are copiously produced in the solid. We therefore equate the melting temperature, \( T_m \), to \( T_{cr} \).

The line tension, i.e., the dislocation self-energy per unit length, is assumed to be that of a dislocation in a complex array, or tangle, of other dislocations. In that case the stress field of a given dislocation beyond \( \approx R/2 \), where \( R \) is the mean interdislocation separation, is largely cancelled out by the stress fields of the other dislocations in the complex array [26, 27]. The line tension is then the sum of the core energy plus the elastic energy inside a cylinder of radius \( R/2 \) [26]:

\[
\sigma = \kappa \frac{G b^2}{4 \pi} \ln \left( \frac{\alpha R}{b} \frac{R}{2} \right) = \kappa \frac{G b^2}{8 \pi} \ln \left( \frac{\alpha^2}{4 b^2 \rho} \right). \tag{19}
\]

Here, \( \kappa \) is 1 for a screw dislocation and \((1 - \nu)^{-1} \approx 3/2\) for an edge dislocation, \( \nu \) being the Poisson ratio. Also, \( G \) is the shear modulus, \( b \) is the Burgers vector magnitude, and \( \alpha \) is a constant of order unity. In the second half of this equation we have taken distance \( R \) to be approximately equal to \( 1/\sqrt{\rho} \), where \( \rho \) is the dislocation density defined in Eq. (18). An expression of the form (19) with \( R = \rho^{-1/2} \) for the dislocation self-energy was originally proposed by Mizushima [8], later put on a sound theoretical basis by Yamamoto and Izuyama [17], and was recently employed by Kierfeld and Vinokur [18] to model dislocation-mediated phase transitions of vortex-line lattices in high-\( T_c \) superconductors.

The constant \( \alpha \) accounts for the nonlinear elastic effects in the dislocation core. Hirsh and Lothe [26] compare dislocation energies in the Peierls-Nabarro (discrete) and Volterra (continuum) dislocation models and find

\[
\frac{1}{\alpha} = \frac{d}{eb} \left( \frac{\sin^2 \beta}{e^\gamma (1 - \nu)} + \cos^2 \beta \right), \tag{20}
\]

where \( \gamma = (1 - 2\nu)/(1 - \nu) \approx 1/8 \), \( d \) is the interplanar spacing, and \( \beta \) is the angle between the Burgers and sense vectors of the dislocation. In a face-centered cubic (fcc) crystal, the smallest perfect-dislocation Burgers vectors are \( \frac{1}{2}(110)a \), and the primary glide planes are \{111\} with \( d = a/\sqrt{3} \), where \( a \) is the lattice constant. Experimental evidence (ref. [20], Table 9-2, p. 275) suggests that the predominant high-temperature glide system in body-centered cubic (bcc) lattices is \{110\}, which has \( d = a/\sqrt{2} \). The smallest bcc perfect-dislocation Burgers vectors are \( \frac{1}{2}(111)a \). Thus, in both cases \( d/b = \sqrt{2}/3 \). Averaging over \( \beta \), we find \( \alpha \approx 2.9 \) for both fcc and bcc lattices. Atomistic calculations of core energies in ionic crystals (ref. [20], p. 232) indicate that \( \alpha \approx 3 \). In metals, no such calculations have been performed. We use \( \alpha = 2.9 \) for all elements.

We have also assumed that no backtracking is allowed for dislocations, \( z' = z - 1 \), since each backtracking would result in a divergence in the linear elastic interaction energy.
between the overlapping segments. The coordination numbers for the elements considered in our analysis below are \( z = 6 \) for a simple cubic (sc) lattice, \( z = 8 \) for bcc and body-centered tetragonal (bct) lattices, and \( z = 12 \) for fcc, hexagonal close-packed (hcp), and double hcp (dhcp) lattices. Replacing

\[
b^3 \equiv \lambda v_{WS},
\]

where \( v_{WS} \) is the volume of the Wigner-Seitz cell of the crystal lattice and \( \lambda \) is a geometric constant, we finally obtain our formula for the melting temperature of the elements:

\[
T_m = \frac{\lambda G v_{WS}}{4 \pi \delta \ln(z - 1)}, \quad \delta^{-1} \equiv \kappa \ln \left( \frac{1.45}{b \sqrt{\rho(T_m)}} \right). \quad (21)
\]

In ref. [19] we evaluated \( G v_{WS}/4\pi T_m \ln(z - 1) \) for 51 elements and found \( \delta/\lambda \) to be \( 1.01 \pm 0.17 \), where the error is the root-mean-square deviation. These \( \delta/\lambda \) are summarized in Fig. 1.

Fig. 1. Values of \( \delta/\lambda = G v_{WS}/4\pi T_m \ln(z - 1) \) from experimental data for 51 elements.
We now assume that the dislocation ensemble is dominated by perfect dislocations, since dislocation energy is proportional to \( b^2 \). For a bcc crystal \( b = a\sqrt{3}/2, v_{WS} = a^3/2, \) and \( b = a/\sqrt{2}, v_{WS} = a^3/4 \) for a fcc crystal. Then, \( b^3 \approx 1.30 v_{WS} \) and \( 1.41 v_{WS} \), respectively. For a hcp lattice, \( \lambda = (4/\sqrt{3})(c/a)^{-1} \), so that for an ideal hcp crystal \( (c/a) \) parts we find

\[
\lambda = \frac{1}{\sqrt{3}}.
\]

Hence, using Eq. (19) with \( R \)

\[
\text{To calculate the free energy of a dislocation ensemble, Eq. (15), let us rewrite Eqs. (10)}.
\]

We regard Eq. (24) as a new dislocation melting law.

4 Free energy of the dislocation ensemble

To calculate the free energy of a dislocation ensemble, Eq. (15), let us rewrite Eqs. (10) and (12), using Eq. (19) with \( R = 1/\sqrt{\rho} \), and replace the sums (which start with \( L = 4b \), the smallest loop length) by the corresponding integrals:

\[
Z_1 = \frac{V}{b^3} A(q, z') \int_{q}^{\infty} dx x^{-q-1} \left[ \frac{4b^2 \rho}{\alpha^2} (z')^{1/c} \right]^{cx},
\]

\[
\xi(T) = A(q, z') \int_{q}^{\infty} dx x^{-q} \left[ \frac{4b^2 \rho}{\alpha^2} (z')^{1/c} \right]^{cx}, \quad c \equiv \frac{\kappa Gb^3}{8\pi k_B T}.
\]

Here, \((4b^2 \rho/\alpha^2)^{(z')^{1/c}} = \exp \{-8\pi \sigma_{\text{eff}}/\kappa G b^2 \} \leq 1, \) since \( \sigma_{\text{eff}} \geq 0 \). Integrating Eq. (25) by parts we find

\[
Z_1 = \frac{V}{q b^3} \left( \frac{\kappa G b^3}{8\pi k_B T} \ln \left[ \frac{4b^2 \rho}{\alpha^2} (z')^{1/c} \right]^{cx} \xi(T) + \frac{A(q, z')}{4q} \left[ \frac{4b^2 \rho}{\alpha^2} (z')^{1/c} \right]^{4ce} \right)
\]

\[
= \frac{V}{q b^3} \left[ -\frac{\sigma_{\text{eff}} b}{k_B T} \xi(T) + \frac{A(q, z')}{4q} e^{-4\sigma_{\text{eff}} b/k_B T} \right].
\]

Hence,

\[
F = -k_B T e^{\mu/k_B T} Z_1 = \frac{V}{q b^3} \left( \sigma_{\text{eff}} \rho b^3 - A(q, z') e^{\mu/k_B T} k_B T e^{-4\sigma_{\text{eff}} b/k_B T} \right),
\]

8
where we have replaced \((\kappa G b^3/8\pi) \ln(\alpha^2/4b^2\rho) - k_B T \ln z'\) by \(b\sigma_{\text{eff}}\), in view of (1),(19), and used Eq. (18).

The second term on the right-hand side of Eq. (28) takes its largest value at \(T = T_m\), where \(\sigma_{\text{eff}} = 0\). To estimate its contribution to the free energy, consider the case of Cu discussed in more detail below. In this case, to estimate \(A(q, z') \exp\{\mu(T_m)/k_B T_m\}/4^q\), we use Eqs. (12),(18), and replace the sum by an integral:

\[
\frac{A(q, z')e^{\mu(T_m)/k_B T_m}}{4^q} = \frac{A(q, z')b^2 \rho(T_m)}{4^q} = \frac{b^2 \rho(T_m)}{4^q} \int_0^\infty dx x^{-q} = \frac{b^2 \rho(T_m)(q-1)}{4}.
\]

As discussed in Section 2, the value of \(q\) may be expected between 3/2 (Brownian loops) and \(\approx 7/4\) (self-avoiding loops). With \(b^2 \rho(T_m)\) given in Eq. (23), we therefore obtain \(A(q, z') \exp\{\mu(T_m)/k_B T_m\}/4^q = 0.095 \pm 0.037 \approx 0.1\).

Hence, the contribution of the second term to \(qF/V\) would be \(\approx -0.7\) meV \(\AA^{-3}\). As seen in Fig. 2, this contribution is negligibly small. In fact, the second zero of \(F\) for \(T = T_m\) and \(A(q, z') \exp\{\mu(T_m)/k_B T_m\}/4^q = 0.1\) occurs at \(b^2 \rho = 0.61\), which is within \(\approx 5\%\) of the value of 0.64 (the second zero of \(F\) at \(T = T_m\) with \(F/V\) given in (29)), and within uncertainties in the values of \(b^2 \rho(T_m)\) in Eq. (23).

Thus, we have derived the dislocation free energy density, and it is given approximately by

\[
\frac{qF(\rho)}{V} \approx \sigma_{\text{eff}} \rho = -\left(\frac{\kappa G}{8\pi} \ln \left(\frac{4b^2 \rho}{\alpha^2}\right) + \frac{k_B T}{b^3} \ln(z-1)\right) b^2 \rho.
\]

This form for the free energy density was previously suggested but not derived by Cotterill [15]. It was later put on a firm theoretical basis by Yamamoto and Izyumaya [17]. It also is a fundamental ingredient in the recently developed theory of dislocation-mediated phase transitions of vortex-line lattices in high-\(T_c\) superconductors [18].

In Fig. 2 we plot \(qF(\rho)/V\) from (29) for Cu for three different temperatures: \(T < T_m\), \(T = T_m\) and \(T > T_m\). We take \(k = 6/5\), \(\alpha = 2.9\), \(G = 47.7\) GPa [28], \(T_m = 1356\) K, and \(b = 2.55\) Å [19]. A first-order phase transition, that is melting, takes place when the second zero of \(F(\rho)\) occurs at the critical dislocation density, \(\rho(T_m)\). This is a transition from a perfect crystalline solid to a highly dislocated solid, not a liquid. In fact, our theory describes dislocations, which do not exist in liquids. If a dislocation is viewed as a disclination dipole [29], the dislocated solid may in turn undergo a Kosterlitz-Thouless-like transition [30] to a phase of free disclinations, i.e., a liquid. This dislocated solid may then be viewed as the three-dimensional analog of an intermediate hexatic phase, between a solid and a liquid, in the Halperin-Nelson theory of two-dimensional melting [31]. The clarification of this point needs further investigation, to be undertaken elsewhere. Patashinskii et al. [14] also identified melting as a transition from a perfect crystalline solid to a highly dislocated solid, and Nelson and Toner [32] found residual bond-orientational order in a three-dimensional solid with an equilibrium concentration of unbound dislocation loops, which is analogous to that in the two-dimensional hexatic phase.

Note that it is not possible to increase the dislocation density progressively from zero to \(\rho(T_m)\) at a temperature lower than \(T_m\) (e.g., by deformation) because of the high
energy barrier at the maximum of $qF(\rho)/V$. Hence, the dislocation density, as a function of temperature, is

$$
\rho(T) = \begin{cases} 
0, & T < T_m, \\
\rho(T_m), & T = T_m.
\end{cases}
$$

(30)

In fact, it can be shown that (30) is the only physical solution of (12) written as a "gap" equation:

$$
e^{-\mu/k_B T}b^2\rho(T) = A(q, z') \sum_{n=4}^{\infty} \frac{(z')^n}{n^q} \left( \frac{4b^2\rho(T)}{\alpha^2} \right)^{\kappa Gb^3n/8\pi k_B T}.
$$

Fig. 2. $qF(\rho)/V$ for Cu at three different temperatures, in units of meV Å$^{-3}$. The vertical line denotes the critical dislocation density value of 0.64 b$^{-2}$.

## 5 Latent heat of fusion

For the ensemble of strings on a lattice considered in Section 2, the internal energy and pressure are

$$
U = -\left( \frac{\partial \ln Z}{\partial \beta} \right) e^{\mu/k_B T} = -\frac{\bar{N}}{Z_1} \frac{\partial Z_1}{\partial \beta} = e^{\mu/k_B T} V \sigma \frac{V\xi(T)}{b^2},
$$

(31)
\[ P = k_B T \left( \frac{\partial \ln Z}{\partial V} \right)_{T,\mu} = k_B T \frac{\dot{N}}{Z_1} \frac{\partial Z_1}{\partial V} = e^{\mu/k_B T} \frac{k_B T}{b^3} \bar{\xi}(T). \]  

(32)

Hence, the enthalpy is

\[ H = U + PV = \frac{V}{b^3} e^{\mu/k_B T} \left[ \sigma b \xi(T) + k_B T \bar{\xi}(T) \right]. \]  

(33)

The latent heat of fusion is the enthalpy difference:

\[ L_m \equiv H(T_m) - H(0). \]  

(34)

In our case, \( H(0) = 0 \), which follows directly from (30)-(33) and Eq. (18). Using \( \sigma_{\text{eff}}(T_m) = 0 \) and the melting condition \( k_B T_m = \sigma b / \ln(z - 1) \), we obtain

\[ L_m = \frac{V}{b^3} e^{\mu(T_m)/k_B T_m} e^{\mu/k_B T_m} \frac{k_B T_m}{b^3} \left[ \ln(z - 1) \xi(T_m) + \bar{\xi}(T_m) \right]. \]  

(35)

To obtain the latent heat per mole, the quantity tabulated in the literature, one has to multiply the expression (35) by the ratio of the number of atoms per mole, \( N_A \), to the total number of atoms in the volume \( V \), which is equal to \( V / v_{WS} \). Replacing \( N_A k_B \) by the gas constant \( R \), and using \( b^3 = \lambda v_{WS} \), we obtain

\[ L_m = \frac{e^{\mu(T_m)/k_B T_m}}{\lambda} \xi(T_m) RT_m \ln(z - 1) \left[ 1 + \frac{1}{\ln(z - 1)} \frac{\bar{\xi}(T_m)}{\xi(T_m)} \right]. \]  

(36)

To estimate the ratio \( \bar{\xi}(T_m)/\xi(T_m) \), we replace the sums in Eqs. (12),(13) by the corresponding integrals:

\[ \frac{\bar{\xi}(T_m)}{\xi(T_m)} = \frac{\int_{L/b=4}^{\infty} d(L/b) (L/b)^{-q} \xi(T_m)}{\int_{L/b=4}^{\infty} d(L/b) (L/b)^{-q}} = \frac{q - 1}{4q}. \]  

(37)

With \( 3/2 \leq q \leq 7/4 \), as discussed in Section 2, \( 0.083 \leq (q - 1)/4q \leq 0.107 \), i.e.,

\[ \frac{\bar{\xi}(T_m)}{\xi(T_m)} = 0.095 \pm 0.012. \]  

(38)

Therefore, the contribution of the second bracketed term on the right-hand side of Eq. (36) (corresponding to the work contribution to enthalpy) is 0.04 – 0.06 \( (6 \leq z \leq 12) \). We expect, therefore, that neglecting the second bracketed term on the right-hand side of Eq. (36) will introduce an error not larger than \( \sim 6\% \). Hence, with accuracy of \( \sim 94\% \) we have the following formula for the latent heats of the elements:

\[ L_m = \frac{1}{\lambda} b^2 \rho(T_m) RT_m \ln(z - 1), \]  

(39)

where we have replaced \( e^{\mu(T_m)/k_B T_m} \xi(T_m) \) by \( b^2 \rho(T_m) \), in view of (18). The proportionality of latent heat of fusion to the critical concentration of defects (multiplied by the core energy) has been noted previously by Cotterill [15].
In Fig. 3 we plot the values of $b^2 \rho(T_m)$ extracted from the experimental data on latent heats for 75 elements. For this analysis, the values of both $T_m$ and $L_m$ are mostly taken from [33]. For Be, Hf, Sc, Sr, Y, the lanthanides Dy, Ce, Er, Gd, Ho, La, Nd, Sm, Tb, Yb, and the actinides Am, Cm, Th, we disregard their high-$T$ bcc phases which exist only in the very vicinity of melting. (The intermediate hcp→fcc phase transition for Yb, dhcp→fcc for Am, Ce and La, and fcc→hcp for Sr, as well as hcp→fcc for Co, do not change coordination number.) The crystal structure chosen for the evaluation of Ca, Co, Mn, N, Np, O, Sm, Ti, Ti, U and Zr corresponds to the phase from which melting occurs. The data on both $T_m$ and $L_m$ for H, N, O, Pa and Rn are taken from [34]. The data on both $T_m$ and $L_m$ for Am and Cm, and on $L_m$ for Ar, Kr, Ne and Xe are taken from [35]. The data on $L_m$ for the lanthanides are taken from [36]. The following values of $\lambda$ are used: 1 for sc, 1.3 for bcc, 1.41 for fcc, 1.24 for Zn, 1.42 for Mg, and 1.33 for all other elements.

Fig. 3. Critical dislocation density as extracted from the experimental data on latent heat of fusion for 75 elements.
For all these elements we find
\[ \rho(T_m) = (0.66 \pm 0.11) b^{-2}, \] (40)
where the error is the root-mean-square deviation. This value is in good agreement with that obtained from the melting temperatures alone, Eq. (23).

Note that the possible inaccuracy in the value of \( \lambda \) for the hcp, dhcp and bct elements used in this analysis, on the order of \( \sim 7\% \), may slightly increase uncertainty in the value of \( \rho(T_m) \) in Eqs. (23) and (40).

We do not have a reasonable explanation for the anomalously high values of \( \rho(T_m) \) for the noble gases. If the noble gases are excluded from the analysis, then \( \rho(T_m) \) turns out to be \( (0.63 \pm 0.06) b^{-2} \) for the remaining 70 elements. Note also that for deuterium (D), which is not included in Fig. 3, with the data on \( T_m \) and \( L_m \) from [35], we obtain \( b^2 \rho(T_m) = 0.70 \).

The uncertainty-weighted average of the values of \( \rho(T_m) \) given in Eqs. (23) and (40) is
\[ \rho(T_m) = (0.64 \pm 0.14) b^{-2}, \] (41)
which we take as our result for the critical dislocation density at melt.

6 Volume change at melt

As an independent consistency check on the relations (23) and (40), we determine the critical dislocation density using the formula [13, 37]
\[ \varepsilon \equiv \frac{\Delta V}{V} = \frac{\lambda}{2\pi} \frac{G}{B} \left( \gamma_G - \frac{1}{3} \right) b^2 \rho(T_m), \] (42)
where \( \Delta V \) is the difference between the liquid and solid specific volumes at melt, \( G \) and \( B \) are the shear and bulk moduli, respectively, and \( \gamma_G \) is the Grüneisen constant. Here, \( \varepsilon \) is identified with the dilation of the lattice as the reaction of the crystal to the sudden proliferation of dislocations. In Table 1 we show the values of \( b^2 \rho(T_m) \) calculated for 32 elements for which we could find zero-pressure data on \( \gamma_G \) and \( \varepsilon \). The experimental values of \( \varepsilon \) are mostly taken from ref. [25], and those of \( G, B \) and \( \gamma_G \) from [28]. For Ar, Kr, Ne and Xe, the values of \( G \) and \( B \) are taken from [38], and those of \( \gamma_G \) from [3].
Table 1. Values of $b^2 \rho(T_m)$ from experimental data on volume change at melt for 32 elements. For comparison, we also show values of $b^2 \rho(T_m)$ extracted for the same elements from the data on latent heats.

For all 32 elements in Table 1 we find

$$\rho(T_m) = (0.51 \pm 0.11) b^{-2},$$

(43)

where the error is the root-mean-square deviation. This is somewhat lower than but still in agreement with both Eqs. (23) and (40) taking into account uncertainties associated with the three values.

For comparison, we show in the last column of Table 1 the values of $b^2 \rho(T_m)$ extracted for the same elements from the data on $L_m$. It is seen that the agreement between two sets of the values of $b^2 \rho(T_m)$ is reasonably good, except for Ag, Al, Cs, Cu, Ni, Pb and Xe, for which the difference in both values of $b^2 \rho(T_m)$ is on the order of $\sim 50 - 60\%$, Lu, Ne and Nd for which the difference is $\sim 45\%$, and Ar, Kr, Pd and Tm, for which it is $\sim 35\%$. For all other elements, the difference does not exceed $\sim 30\%$.

Note that the contribution of the volume change at melt, \( \varepsilon \), to the latent heat of fusion is proportional to \( \varepsilon^2 \ll 1 \) \cite{33,37}, and is therefore negligibly small compared to the right-hand side of Eq. (39).

### 7 Concluding remarks

Our theory of dislocation-mediated melting was developed in the approximation that dislocations are non-interacting. This approximation is good only in the vicinity of melt where the dislocation density is very high and the otherwise long-range interactions are sufficiently screened \cite{27}. The statistical mechanics of non-interacting dislocations on a lattice yields simple, accurate relations between the dislocation density at melt and both the melting temperature and latent heat of fusion, despite the indeterminacy of the parameter \( q \) that takes into account the possible non-Brownian nature of the dislocation network. The values of \( \rho(T_m) \), as determined from an extensive analysis of \( T_m \) and \( L_m \) data, are remarkably consistent: \( (0.61 \pm 0.20) b^{-2} \) and \( (0.66 \pm 0.11) b^{-2} \), respectively. The uncertainty-weighted average of these values is \( \rho(T_m) = (0.64 \pm 0.14) b^{-2} \), which we take as our result for the dislocation density at melt. Poirier and Price \cite{13} analyzed their result corresponds to \( \rho \) network. The values of \( \rho \) parameter \( q \), both the melting temperature and latent heat of fusion, despite the indeterminacy of the parameter \( q \) that takes into account the possible non-Brownian nature of the dislocation network.

The uncertainty-weighted average of these values is \( \rho(T_m) = (0.64 \pm 0.14) b^{-2} \), which we take as our result for the dislocation density at melt. Poirier and Price \cite{13} analyzed 14 elements and found \( \rho(T_m)v_{WS}/b = 0.48 \pm 0.12 \). Using \( v_{WS} = b^3/\lambda \) with \( \lambda \approx 4/3 \), their result corresponds to \( \rho(T_m) = (0.64 \pm 0.16) b^{-2} \), which is in excellent agreement with ours. Kierfeld and Vinokur \cite{18} modelled dislocation-mediated phase transitions of a vortex-line lattice and found \( \rho(T_m) \approx 0.6 b^{-2} \). Vachaspati’s \cite{10} study of topological defect formation gave \( a^2 \rho(T_m) \approx 0.88 \) for a simple cubic lattice. This translates into \( \rho(T_m) \approx 0.66 b^{-2} \) for bcc lattices \( (a = 2/\sqrt{3} \ b) \) and \( \rho(T_m) \approx 0.44 b^{-2} \) for fcc lattices \( (a = \sqrt{2} b) \), which are consistent with our result. In agreement with Vachaspati, Kibble \cite{11} found \( a^2 \rho(T_m) \approx 0.89 \) for a simple cubic lattice.

Although our main results do not depend on the precise value of \( q \), there is a particular value of \( q \) at which the relations (29) and (39) become exact: \( q = 1 \). In this limit, as seen in (12), \( \xi(T_m) \to \infty \), so that Eq. (39) becomes exact in view of (36). Requiring finite internal energy in this limit leads, via (31), to \( \exp\{\mu(T_m)/k_B T_m\} \to 0 \ (\mu(T_m) \to -\infty) \), and therefore, Eq. (29) becomes exact, since the second term on the right-hand side of (28) disappears. In fact, the study of cosmological networks of string loops in 3 dimensions by Magueijo, Sandvik and Steer \cite{12} results in a scale-invariant loop distribution of the form of Eqs. (9),(10) with \( q + 1 < 5/2 \) : \cite{13} \( 1.9 < q + 1 < 2.1 \), or \cite{14} \( q + 1 = 2.03 \) (plus error bars), and so in this study \( q \approx 1 \). Thus, it is quite possible that linear defects which correspond to two apparently distinct physical phenomena, namely cosmic strings and crystal dislocations, are of a very similar statistical-mechanical nature.

The average total dislocation length per Wigner-Seitz cell at melt is \( \rho(T_m)v_{WS} = b \rho(T_m)/\lambda \approx b/2 \), since \( \lambda \approx 4/3 \). Since a Wigner-Seitz cell contains \( z \) links, each of length \( b/2 \), it follows that, on average, one of \( z \) links in each Wigner-Seitz cell is covered by a dislocation. Since each such a link is shared between two atoms, on average, half of the atoms are within a dislocation core at melt.

If we use \( \rho(T_m) = 0.64 b^{-2} \), then to \( \sim 20\% \) accuracy the melting temperatures and
latent heats are given by

\[ k_B T_m = \frac{G \nu W S}{4\pi \ln(z - 1)}, \]  

(44)

\[ L_m = \frac{\ln(z - 1)}{2} R T_m. \]  

(45)

The accuracy of these relations depends critically on the factor of \( \ln(z - 1) \), which is characteristic of a theory based on line-like degrees of freedom.
