We consider \( n \) identically prepared qubits and study the asymptotic properties of the joint state \( \rho ^{\otimes n} \). We show that for all individual states \( \rho \) situated in a local neighborhood of size \( 1/\sqrt{n} \) of a fixed state \( \rho_0 \), the joint state converges to a displaced thermal equilibrium state of a quantum harmonic oscillator. The precise meaning of the convergence is that there exist physical transformations \( T_n \) (trace preserving quantum channels) which map the qubits states asymptotically close to their corresponding oscillator state, uniformly over all states in the local neighborhood.

A few consequences of the main result are derived. We show that the optimal joint measurement in the Bayesian set-up is also optimal within the pointwise approach. Moreover, this measurement converges to the heterodyne measurement which is the optimal joint measurement of position and momentum for the quantum oscillator. A problem of local state discrimination is solved using local asymptotic normality.

PACS numbers:

1. INTRODUCTION

Quantum measurement theory brings together the quantum world of wave functions and incompatible observables with the classical world of random phenomena studied in probability and statistics. These fields have come ever closer due to the technological advances making it possible to perform measurements on individual quantum systems. Indeed, the engineering of a novel quantum state is typically accompanied by a verification procedure through which the state, or some aspect of it, is reconstructed from measurement data [1].

An important example of such a technique is that of quantum homodyne tomography in quantum optics [2]. This allows the estimation with arbitrary precision of the whole density matrix \( \rho \) of a monochromatic beam of light by repeatedly measuring a sufficiently large number of identically prepared beams [1, 7, 8].

In contrast to this “semi-classical” situation in which one fixed measurement is performed repeatedly on independent systems, the state estimation problem becomes more “quantum” if one is allowed to consider joint measurements on \( n \) identically prepared systems with joint state \( \rho ^{\otimes n} \). It is known [2] that in the case of unknown mixed states \( \rho \), joint measurements perform strictly better than separate measurements in the sense that the asymptotical convergence rate of the optimal estimator \( \hat{\rho} \) to \( \rho \) goes in both case as \( C/\sqrt{n} \) with a strictly smaller constant \( C \) in the case of joint measurements.

Let us look at this problem in more detail: we dispose of a number of \( n \) copies of an unknown state \( \rho \) and the task is to estimate \( \rho \) as well as possible. The first step is to specify a cost function \( d(\hat{\rho}, \rho) \) which quantifies the deviation of the estimator \( \hat{\rho} \) from the true state. Then one tries to devise a measurement and an estimator which minimizes the mean cost or risk in statistics jargon:

\[
R(\rho, \hat{\rho}) := \langle d(\hat{\rho}(X), \rho) \rangle,
\]

with the average taken over the measurement results \( X \). Since this quantity still depends on the unknown state one may choose a Bayesian approach and try to optimize the average risk with respect to some prior distribution \( \pi \) over the states

\[
R_{n, \pi} = \int R(\rho, \hat{\rho}) \pi(d\rho).
\]

Results of this type have been obtained in both the pure state case [10, 11, 12, 13, 14, 15, 16, 17] and the mixed state case [18, 19, 20, 21, 22, 23]. However most of these papers use methods of group theory which depend in on the symmetry of the prior distribution and the form of the cost function, and thus cannot be extended to arbitrary priors.

In the pointwise approach [1, 27, 21, 27, 28, 29] one tries to minimize \( R(\rho, \hat{\rho}) \) for each fixed \( \rho \). We can argue that even for a completely unknown state, as \( n \) becomes large the problem ceases to be global and becomes a local one as the error in estimating the state parameters is of the order \( 1/\sqrt{n} \). For this reason it makes sense to parametrize the state as \( \rho := \rho(\theta) \) with \( \theta \) belonging to some set in \( \mathbb{R}^k \) and to replace the original cost with its quadratic approximation at \( \theta \):

\[
d(\theta, \hat{\theta}) = (\theta - \hat{\theta})^T G(\theta)(\theta - \hat{\theta}),
\]

where \( G \) is a \( k \times k \) positive, real symmetric weight matrix.

Although seemingly different, the two approaches can be compared [30], and in fact for large \( n \) the prior distribution \( \pi \) of the Bayesian approach should become increasingly irrelevant and the optimal Bayesian estimator should be close to the maximum likelihood estimator. An instance of this asymptotic equivalence is proven in Subsection 7.4.

In this paper we change the perspective and instead of trying to devise optimal measurements and estimators for a particular statistical problem, we concentrate our
attention on the family of joint states $\rho_n(\theta)^\otimes n$ which is the primary “carrier” of statistical information about $\theta$. As suggested by the locality argument sketched above, we consider a neighborhood of size $\frac{1}{\sqrt{n}}$ around a fixed but arbitrary parameter $\theta_0$, whose points can be written as $\theta = \theta_0 + u/\sqrt{n}$ with $u \in \mathbb{R}^k$ the “local parameter” obtained by zooming into the smaller and smaller balls by a factor of $\sqrt{n}$. Very shortly, the principle of local asymptotic normality says that for large $n$ the family

$$\rho_n^u := \rho(\theta_0 + u/\sqrt{n})^\otimes n, \quad ||u|| < C,$$

converges to a family of displaced Gaussian states $\phi^u$ of a of a quantum system consisting of a number of coupled quantum and classical harmonic oscillators.

The term local asymptotic normality comes from mathematical statistics [31] where the following result holds. We are given independent variables $X_1, \ldots, X_n \in \mathcal{X}$ drawn from the same probability distribution $P^{\theta_0+n/\sqrt{n}}$ over $\mathcal{X}$ depending smoothly on the unknown parameter $u \in \mathbb{R}^k$. Then the statistical information contained in our data is asymptotically identical with the information contained in a single normally distributed $Y \in \mathbb{R}^k$ with mean $u$ and variance $I(\theta_0)^{-1}$, the inverse Fisher information matrix. This means that for any statistical problem we can replace the original data $X_1, \ldots, X_n \in \mathcal{X}$ by the simpler Gaussian one $Y$ with the same asymptotic results!

For the sake of clarity let us consider the case of qubits with states parametrized by their Bloch vectors $\rho(\vec{\sigma}) = \frac{1}{2}(1 + \vec{\sigma} \cdot \vec{\sigma})$ where $\vec{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ are the Pauli matrices. Define now the two-dimensional family of joint states obtained by rotating the Bloch vector $\vec{r}_0 = (0, 0, 2\mu - 1)$ around an axis in the x-y plane

$$\rho_n^u = \left[ U \left( \frac{u}{\sqrt{n}} \right) \begin{pmatrix} \mu & 0 \\ 0 & 1 - \mu \end{pmatrix} U \left( \frac{u}{\sqrt{n}} \right)^\dagger \right]^\otimes n, \quad u \in \mathbb{R}^2,$$

with unitary $U(v) := \exp(i(v_x \sigma_x + v_y \sigma_y))$ and $\frac{1}{2} < \mu \leq 1$.

Consider now a quantum harmonic oscillator with position and momentum operators $Q$ and $P$ on $L^2(\mathbb{R})$ satisfying the commutation relations $[Q, P] = i\mathbf{1}$. We denote by $\{|n\}, n \geq 0\}$ the eigenbasis of the number operator and define the thermal equilibrium state

$$\phi^0 = (1 - p) \sum_{k=0}^{\infty} p^k |k\rangle\langle k|,$$

where $p = \frac{1 - \mu}{\mu}$. We translate the state $\phi^0$ by using the displacement operators $D(\mathbf{z}) = \exp(\mathbf{za}^* - \mathbf{za})$ with $\mathbf{z} \in \mathbb{C}$ which map the ground state $|0\rangle$ into the coherent state $|\mathbf{z}\rangle$:

$$\phi^u := D(\sqrt{2\mu - 1} \alpha_0)\phi^0 D(\sqrt{2\mu - 1} \alpha_0)^*, \quad (1.2)$$

where $\alpha_0 := -u_y + iu_z$.}

**Theorem 1.1** Let $\rho_n^u$ be the family of states (1.1) on the Hilbert space $(\mathbb{C}^2)^\otimes n$ and $\phi^0$ the family (1.2) of displaced thermal equilibrium states of a quantum oscillator. Then for each $n$ there exist quantum channels (trace preserving CP maps)

$$T_n : M \left( (\mathbb{C}^2)^\otimes n \right) \rightarrow \mathcal{T}(L^2(\mathbb{R})), \quad S_n : \mathcal{T}(L^2(\mathbb{R})) \rightarrow M \left( (\mathbb{C}^2)^\otimes n \right),$$

with $\mathcal{T}(L^2(\mathbb{R}))$ the trace-class operators, such that

$$\lim_{n \to \infty} \sup_{u \in \mathbb{R}^2} ||\phi^u - T_n(\rho_n^u)||_1 = 0, \quad \lim_{n \to \infty} \sup_{u \in \mathbb{R}^2} ||\rho_n^u - S_n(\phi^u)||_1 = 0.$$  

for an arbitrary bounded interval $I \subset \mathbb{R}$.

Let us make a few comments on the significance of the above result.

i) The “convergence” (1.1) of the qubit states holds in a strong way (uniformly in $u$) with direct statistical and physical interpretation. Indeed the channels $T_n$ and $S_n$ represent physical transformations which are analogues of randomizations of classical data [31]. The meaning of (1.2) is that the two quantum models are asymptotically equivalent from a statistical point of view.

ii) Indeed for any measurement $M$ on $L^2(\mathbb{R})$ we can construct the measurement $M \circ T_n$ on the spin states by first mapping them to the oscillator space and then performing $M$. Then the optimal solution of any statistical problem concerning the states $\rho_n^u$ can be obtained by solving the same problem for $\phi^0$ and pulling back the optimal measurement $M$ as above. We illustrate this in Section 7 for the estimation problem and for hypothesis testing.

iii) The proposed technique may be useful for applications in the domain of coherent spin states [32] and squeezed spin states [33]. Indeed, it has been known since Dyson [34] that $n$ spin-$\frac{1}{2}$ particles prepared in the spin up state $|\uparrow\rangle^\otimes n$ behave asymptotically as the ground state of a quantum oscillator when considering the fluctuations of properly normalized total spin components in the directions orthogonal to $z$. Our Theorem extends this to spin directions making an “angle” $u/\sqrt{n}$ with the $z$ axis, as well as to mixed states, and gives a quantitative expression to heuristic pictures common in the physics literature (see Section 8). We believe that a similar approach can be followed in the case of spin squeezed states and continuous time measurements with feedback control [35].

Next Section gives an introduction to the statistical ideas motivating our work. In Section 8 we give a heuristic picture of our main result based on a total spin vector representation of spin coherent states familiar in the physics literature.
The proof of Theorem 1.1 extends over the Sections 4.4.6 and uses methods of group theory and some ideas from 29, 30, 35, 36, 37, 38.

Section 4 describes a few applications of our main result. In Subsection 7.1 we compute the local asymptotic minimax risk for the statistical problem of qubit state estimation. An estimation scheme which achieves this risk asymptotically is optimal in the pointwise approach. We show that this figure of merit coincides with the risk of the heterodyne measurement and that it is achieved by the optimal Bayesian measurement for the SU(2)-invariant prior 24, 25. This proves the asymptotic equivalence of the Bayesian and pointwise approaches.

In Subsection 7.3 we continue the investigation of the optimal Bayesian measurement and show that it converges locally to the heterodyne measurement on the oscillator which is a optimal joint measurement of position and momentum 24.

Another application is the problem discriminating between two states $\rho_n^{X_0}$ which asymptotically converge to each other at rate $1/\sqrt{n}$. In this case the optimal measurement for the parameter $u$ is not optimal for the testing problem, showing in particular that the quantum Fisher information in general does not encode all statistical information.

2. LOCAL ASYMPTOTIC NORMALITY IN STATISTICS AND ITS EXTENSION TO QUANTUM MECHANICS

In this Section we introduce some statistical ideas which provide the motivation for deriving the main result.

Quantum statistical problems can be seen as a game between a statistician or physicist in our case, and Nature. The latter tries to codify some information by preparing a quantum system in a state which depends on some parameter $u$ unknown to the former. The physicist tries to guess the value of the parameter by devising measurements and estimators which work well for all choices of parameters that Nature may make. In a Bayesian setup Nature may build her strategy by randomly choosing a state with some prior distribution. In order to solve the problem the physicist is allowed to use the laws of quantum physics as well as those of classical stochastics and statistical inference. In particular he may transform the quantum state by applying an arbitrary quantum channel $T$ and obtain a new family $T(\rho^u)$. In general such transformation goes with a loss of information so one should have a good reason to do it but there are non trivial situations when no such loss occurs 40, that is when there exists a channel $S$ which reverses the effect of $T$ restricted to the states of interest $S(T(\rho^u))=\rho^u$. If this is the case the we consider the two families of states $\rho^u$ and $T(\rho^u)$ as statistically equivalent.

In statistics such transformations are called randomizations and a useful particular example is a statistic, which is just a function of the data which we want to analyze. When this statistic contains all information about the unknown parameter we say that it is sufficient, because knowing the value of this statistic alone suffices and given this information, the rest of the data is useless. For example if $X_1,\ldots,X_n \in \{0,1\}$ are results of independent coin tosses with a biased coin, then $X = \frac{1}{n} \sum X_i$ is sufficient statistic and may be used for any statistical decision without loss of efficiency.

Quantum randomizations through quantum channels allows us to compare seemingly different families of states and thus opens the possibility of solving a particular problem by casting it in a more familiar setting. The example of this paper is that of state estimation for $n$ identical copies of a state which can be cast asymptotically into the problem of estimating the center of a Gaussian which has a rather simple solution 39.

The term “asymptotically” means that for large $n$ we can find quantum channels $T_n$, $S_n$ which almost map the the families of states into each other as in equation (1.4).

The second main idea that we want to introduce is that of local asymptotic normality. Back in the coin toss example we have that $X$ is a good estimator of the probability $\mu$ of obtaining a 1 and by the Central Limit Theorem the error $X - \mu$ has asymptotically a Gaussian distribution

$$\sqrt{n}(X - \mu) \sim N(0, 1/\sqrt{n}),$$

in particular the mean error is $\langle (X-\mu)^2 \rangle = 1/(n\mu(1-\mu))$. Now, if for each $n$ the unknown parameter $\mu$ is restricted to a local neighborhood of a fixed $\mu_0$ of size $1/\sqrt{n}$, one might expect an improvement in the error because we know more about the parameter and we can use that information to build better estimators. However this is not entirely true. Indeed if we write $\mu = \mu_0 + u/\sqrt{n}$ then the estimator of the local parameter $u$ is

$$\hat{u}_n = \sqrt{n}(X - \mu_0) \sim N(u, 1/\mu_0(1-\mu_0))$$

which says that the problem of estimating $\mu$ in the local parameter model is as difficult as the original problem, i.e. the variance of the estimator is the same. The reason for this is that the additional information about the location of the parameter is nothing new as we could guess that directly form the data with very high probability. Thus without changing the difficulty of the original problem we can look at it locally and then we see that it transforms into that of estimating the center of a Gaussian with fixed variance $N(u, 1/\mu_0(1-\mu_0))$, which is a classical statistical problem.

In general we can formulate the following principle: given $X_1,\ldots,X_n \in \mathcal{X}$ independent with distribution $P^{\mu_0+u}/\sqrt{n}$ depending smoothly on the unknown parameter $u \in \mathbb{R}^k$, then asymptotically this model is statistically equivalent (there exist explicit randomizations in both directions) with that of a single draw $Y \in \mathbb{R}^k$ from the Gaussian distribution $N(u, I(\theta_0)^{-1})$ with fixed variance equal to the inverse of the Fisher information matrix 31.
In the quantum case we replace the randomizations by quantum channels and the Gaussian limit model by its quantum equivalent which in the simplest case is a family of displaced thermal states of a quantum oscillator (see Theorem 11), but in general is a Gaussian state on a number of coupled quantum and classical oscillators, with canonical variables satisfying general commutation relations [41].

A simple extension of Theorem 11 is obtained by adding an additional local parameter $t \in \mathbb{R}$ for the density matrix eigenvalues such that $\mu = \mu_0 + t/\sqrt{n}$. This leads to a Gaussian limit model in which we are given a quantum oscillator in state $\phi^n$ and additionally, a classical Gaussian variable with distribution $N(t, 1/\mu_0(1 - \mu_0))$. The meaning of this quantum-classical coupling is the following: asymptotically the problem of estimating the eigenvalues decouples from that of estimating the direction of the Bloch vector and becomes a classical statistical problem (identical with the coin toss discussed above), while that of estimating the direction remains quantum and converges to the estimation of a Gaussian state of a quantum oscillator. We note that this decoupling has been also observed in [24, 29].

It is customary to represent the state of two dimensional quantum system by a vector $\vec{r}$ in the Bloch sphere such that the corresponding density matrix is

$$\rho = \frac{1}{2}(1 + \vec{r} \cdot \sigma) = \frac{1}{2}(1 + \sigma_x \sigma_x + \sigma_y \sigma_y + \sigma_z \sigma_z),$$

where $\sigma_i$ represent the Pauli matrices and satisfy the commutation relations $[\sigma_i, \sigma_j] = 2i\epsilon_{ijk} \sigma_k$. In particular if $\vec{r} = (0, 0, \pm 1)$ then the state is given by the spin up $|\uparrow\rangle$ and respectively spin down $|\downarrow\rangle$ basis vectors of $\mathbb{C}^2$, and the $z$-component of the spin $\sigma_z$ takes value $\pm 1$. As for the $x$ and $y$ spin components, each one may take the values $\pm 1$ with equal probabilities such that on average $\langle \sigma_x \rangle = \langle \sigma_y \rangle = 0$ but the variances are $\langle \sigma^2_x \rangle = \langle \sigma^2_y \rangle = 1$. Moreover $\sigma_x$ and $\sigma_y$ do not commute and thus cannot be measured simultaneously.

What happens with the Bloch sphere picture when we have more spins? Consider for the beginning $n$ identical spins prepared in a coherent spin up state $|\uparrow\rangle \otimes n$, then we can think of the whole as a single spin system and define the global observables $L^n_i = \sum_{k=1}^n \sigma_i^{(k)}$ for $i = x, y, z$, where $\sigma_i^{(k)}$ is the spin component in the direction $i$ of the $k$’s spin. Intuitively, we can represent the joint state by a vector of length $n$ pointing to the north pole of a large sphere as in Figure 1. However due to the quantum character of the spin observables, the $x$ and $y$ components cannot be equal to zero and it is more instructive to think in terms of a vector whose tip lies on a small blob of the size of the uncertainties in $x$ and $y$, sitting on the top of the sphere. Exactly how large is this blob? By using the Central Limit Theorem we conclude that in the limit $n \to \infty$ the distribution of the “fluctuation operator”

$$S^{(n)}_x := \frac{1}{\sqrt{2n}} L^{(n)}_x = \frac{1}{\sqrt{2n}} \sum_{k=1}^n \sigma^{(k)}_x,$$

converges to a $N(0, 1/2)$ Gaussian, that is $\langle S^2_x \rangle = 0$ and $\langle S^2_y \rangle \approx 1/2$, and similarly for the component $S^{(n)}_y$. The width of the blob is thus of the order $\sqrt{n}$ in both $x$ and $y$ directions.

Now, the two fluctuations do not commute with each other

$$[S^{(n)}_x, S^{(n)}_y] = \frac{i}{n} L^{(n)}_z \approx i 1,$$

which is the well know commutation relation for canonical variables of the quantum oscillator. In fact the quantum extension of the Central Limit Theorem makes this more precise

$$\lim_{n \to \infty} \otimes n \{ |\uparrow\rangle \prod_{k=1}^p S^{(n)}_{ik} |\uparrow\rangle \otimes n = \Omega, \prod_{k=1}^p X_{ik} \Omega, \forall i_k \in \{ x, y \},$$

where $X_x := Q$ and $X_y := P$ satisfy $[Q, P] = i 1$ and $\Omega$ is the ground state of the oscillator.

The above description is not new in physics and goes back to Dyson’s theory of spin-wave interaction [34]. More recently squeezed spin states [33] for which the variances $\langle S^2_x \rangle$ and $\langle S^2_y \rangle$ of spin variables are different have been found to have important applications various fields such as magnetochemistry [32], entanglement between many particles [42]. The connection with such applications will be discussed in more detail in Section 7.

We now rotate all spins by the same small angle for each particle as in Figure 4. As we will see, it makes sense to scale the angle by the factor $\frac{1}{\sqrt{n}}$ i.e. to consider

$$\psi^n_{u} = \left[ \exp \left( -\frac{i}{\sqrt{n}} (u_x \sigma_x + u_y \sigma_y) \right) |\uparrow\rangle \right] \otimes n, \quad u \in \mathbb{R}^2.$$
Indeed for such angles the $z$ component of the vector will change by a small quantity of the order $\sqrt{n} \ll n$ so the commutation relations remain the same, while the uncertainty blob will just shift its center such that the new averages of the renormalized spin components are $\langle S_x^{(n)} \rangle \approx -\sqrt{2} u_y$ and $\langle S_y^{(n)} \rangle \approx \sqrt{2} u_x$. All in all, the spins state converges to the coherent state $|\alpha_u\rangle$ of the oscillator where $\alpha_u = (-u_y + i u_x) \in \mathbb{C}$ and in general

$$|\alpha\rangle := \exp\left(-|\alpha|^2/2\right) \sum_{j=0}^{\infty} \frac{\alpha^j}{\sqrt{j!}} |j\rangle,$$

with $|j\rangle$ representing the $j$’s energy level.

We consider now the case of qubits in individual mixed states $\rho_k^u \leftarrow |\alpha_k^u\rangle \langle \alpha_k^u |$ with $<1/2\mu < 1$. Then the “length” of $L_z$ is $n(2\mu - 1)$ but the size of the blob is the same (see Figure 3). However the commutation relations

is a thermal equilibrium state

$$\phi^0 = (1 - p) \sum_{k=0}^{\infty} p^k |k\rangle \langle k|, \quad p = \frac{1 - \mu}{\mu}.$$

Finally the rotation by $\exp\left(\frac{\sqrt{n}(u_x \sigma_x + u_y \sigma_y)}{2}\right)$ produces a displacement of the thermal state such that $\langle Q \rangle = -\sqrt{2(\mu - 1)} u_y$ and $\langle P \rangle = \sqrt{2(\mu - 1)} u_x$.

4. LOCAL ASYMPTOTIC NORMALITY FOR MIXED QUBIT STATES

We give now a rigorous formulation of the heuristics presented in the previous Section. Let

$$\rho^0 = \begin{pmatrix} \mu & 0 \\ 0 & 1 - \mu \end{pmatrix}$$

be a density matrix on $\mathbb{C}^2$ with $\mu > 1/2$, representing a mixture of spin up and spin down states, and for every $u = (u_x, u_y) \in \mathbb{R}^2$ consider the state $\rho^u = U(u) \rho^0 U(u)^*$ where

$$U(u) := \exp(i (u_x \sigma_x + u_y \sigma_y)) = \begin{pmatrix} \cos|u| & -e^{-i\varphi} \sin|u| \\ e^{i\varphi} \sin|u| & \cos|u| \end{pmatrix},$$

with $\varphi = \arg(-u_y + i u_x)$. We are interested in the asymptotic behavior as $n \to \infty$ of the family

$$\mathcal{F}_n := \left\{ \rho_n^u = \left(\rho^u / \sqrt{n}\right)^\otimes n, \; u \in I^2 \right\},$$

where $I = [-a, a]$ is a fixed finite interval.

The main result is that $\mathcal{F}_n$ is asymptotically normal, meaning that it converges as $n \to \infty$ to a limit family $\mathcal{G}_n := \{ \phi^u, \; u \in I^2 \}$ of Gaussian states of a quantum oscillator with creation and annihilation operators satisfying $[a, a^*] = 1$.

Let

$$\phi^0 := (1 - p) \sum_{k=0}^{\infty} p^k |k\rangle \langle k|,$$

be a thermal equilibrium state with $|k\rangle$ denoting the $k$’s energy level of the oscillator and $p = \frac{1 - \mu}{\mu} < 1$. For every $u \in I^2$ define

$$\phi^u := D(\sqrt{2(\mu - 1)} a_u) \phi^0 D(\sqrt{2(\mu - 1)} a_u),$$

where $D(z) := \exp(z a^* - z^* a)$ is the displacement operator, mapping the vacuum vector $|0\rangle$ to the coherent vector $|z\rangle$ and $a_u = (-u_y + i u_x)$.

The exact formulation of the convergence is given in Theorem 1.1. Thus the state $\rho^u$ of the $n$ qubits which depends on the unknown parameter $u$ can be manipulated by applying a quantum channel $T_n$ such that its image converges to the Gaussian state $\phi^u$, uniformly in $u \in I^2$. Conversely by using the channel $S_n$, the state $\phi^u$ can be mapped to a joint state of $n$ qubits which is
composed as a mixture of "block" density matrices

\[ T(\rho) = \text{Tr}_K (V \rho V^*), \]
\[ S(\phi) = \text{Tr}_{K'} (W \phi W^*), \]

where the partial traces are taken over some ancillary Hilbert spaces \( K, K' \) and

\[ V : (\mathbb{C}^2)^\otimes n \rightarrow L^2(\mathbb{R}) \otimes K, \]
\[ W : L^2(\mathbb{R}) \rightarrow (\mathbb{C}^2)^\otimes n \otimes K', \]

are isometries (\( V^* V = 1 \) and \( W^* W = 1 \)).

Our task is now to identify the isometries \( V_n \) and \( W_n \) implementing the channels \( T_n \) and respectively \( S_n \) satisfying (14). The first step towards identifying these \( V_n \) is to use group representations methods so as to partially (block) diagonalize all the \( \rho_n^u \) simultaneously.

### A. Block decomposition

In this Subsection we show that the states \( \rho_n^u \) have a block-diagonal form given by the decomposition of the space \((\mathbb{C}^2)^\otimes n\) into irreducible representations of the relevant symmetry groups. The main point is that for large \( n \) the weights of the different blocks concentrate around the representation with total spin \( j_n = n(\mu - 1/2) \).

The space \((\mathbb{C}^2)^\otimes n\) carries a unitary representation \( \pi_n \) of the one spin symmetry group \( SU(2) \) with \( \pi_n(u) = u^\otimes n \) for any \( u \in SU(2) \), and a unitary representation of the symmetric group \( S(n) \) given by the permutation of factors

\[ \pi_n(\tau) : v_1 \otimes \cdots \otimes v_n \mapsto v_{\tau^{-1}(1)} \otimes \cdots \otimes v_{\tau^{-1}(n)}, \quad \tau \in S(n). \]

As \([\pi_n(u), \pi_n(\tau)] = 0\) for all \( u \in SU(2), \tau \in S(n) \) we have the decomposition

\[ (\mathbb{C}^2)^\otimes n = \bigoplus_{j=0,1/2}^{n/2} \mathcal{H}_j \otimes \mathcal{H}_j^*, \quad (4.5) \]

where the direct sum runs over all positive (half)-integers \( j \) up to \( n/2 \), and for each fixed \( j, \mathcal{H}_j \cong \mathbb{C}^{2j+1} \) is an irreducible representation of \( SU(2) \) with total angular momentum \( J^2 = j(j+1) \), and \( \mathcal{H}_j^* \cong \mathbb{C}^{2j} \) is the irreducible representation of the symmetric group \( S(n) \) with \( j_n = (n/2-j) - (n/2-j-1) \). In particular the density matrix \( \rho_n^u \) is invariant under permutations and can be decomposed as a mixture of “block” density matrices

\[ \rho_n^u = \bigoplus_{j=0,1/2}^{n/2} p_n(j) \rho_{j,n}^u \otimes \frac{1}{n_j}, \quad (4.6) \]

with probability distribution \( p_n(j) \) given by (26):

\[ p_n(j) := \frac{n_j}{2\mu - 1} (1 - \mu)^{2-j} \mu^{j+1} (1 - p^{2j+1}), \quad (4.7) \]

where \( p := \frac{1-\mu}{\mu} \). A key observation is that for large \( n \) and in the relevant range of \( j \)'s, \( p_n(j) \) is essentially a binomial distribution

\[ B_{n,\mu}(k) := \binom{n}{k} \mu^k (1-\mu)^{n-k}, \quad k = 0, \ldots, n. \]

Indeed we can rewrite \( p_n(j) \) as

\[ p_n(j) := B_{n,\mu}(n/2 + j) \times K(j,n,\mu) \quad (4.8) \]

where the factor \( K(j,n,\mu) \) is given by

\[ K(j,n,\mu) = \frac{1 - p^{2j+1}}{n + (j - j_n + 1)/\mu} \]

and \( j_n := n(\mu - 1/2) \). As \( B_{n,\mu} \) is the distribution of the sum of independent Bernoulli variables with individual distribution \((1 - \mu, \mu)\) over \( \{0, 1\} \), we can use the central limit Theorem to conclude that its mass concentrates around the average \( \mu n \) with a width of order \( \sqrt{n} \), in other words of any \( 0 < \epsilon < 1/2 \) we have

\[ \lim_{n \rightarrow \infty} \sum_{p=-n^{1/2+\epsilon}}^{n^{1/2+\epsilon}} B_{n,\mu}(\mu n + p) = 1. \quad (4.9) \]

Let us denote by \( J_{n,\epsilon} \) the set of values \( j \) of the total angular momentum of \( n \) qubits which lie in the interval \([j_n - n^{1/2+\epsilon}, j_n + n^{1/2+\epsilon}]\). Then for large \( n \), the factor \( K(j,n,\mu) \) is close to 1 uniformly over \( j \in J_{n,\epsilon} \) and from formulas (4.8), (4.9) we conclude that \( p_n(j) \) concentrates asymptotically in an interval of order \( n^{1/2+\epsilon} \) around \( j_n \):

\[ \lim_{n \rightarrow \infty} p_n(J_{n,\epsilon}) = 1. \quad (4.10) \]

This justifies the big ball picture used in the previous section.

### B. Irreducible representations of \( SU(2) \)

Here we remind the reader some details about the irreducible representation \( \pi_j \) of \( SU(2) \) on \( \mathcal{H}_j \). Let \( \sigma_x, \sigma_y, \sigma_z \) be the Pauli matrices and denote \( \sigma_{j,l} := \pi_j(\sigma_l) \) for \( l = x, y, z \) the generators of rotations in the irreducible representation \( \pi_j \), such that the corresponding unitaries are \( U_j(u) := \exp \{ i(ux J_{j,x} + uy J_{j,y}) \} \). There exists an orthonormal basis \{\( |j, m\rangle, m = -j, \ldots, j \}\) of \( \mathcal{H}_j \) such that

\[ J_{j,z} |j, m\rangle = m |j, m\rangle. \]

Moreover, with \( J_{j,\pm} := J_{j,x} \pm i J_{j,y} \) we have

\[ J_{j,+} |j, m\rangle = \sqrt{j - m} \sqrt{j + m} |j, m + 1\rangle, \]
\[ J_{j,-} |j, m\rangle = \sqrt{j - m + 1} \sqrt{j + m} |j, m - 1\rangle. \]

With these notations and \( p = \frac{1-\mu}{\mu} \) as before, the state \( \rho_{j,n}^0 \) can be written as (26):

\[ \rho_{j,n}^0 = c_j(p) \sum_{m=-j}^{j} p^{j-m} |j, m\rangle \langle j, m|, \]
where the normalizing factor is \( c_j(p) = (1-p)/(1-p^{2j+1}) \).

The rotated block states can be obtained by applying the unitary transformation

\[
\rho_{j,n}^u = U_j(u/\sqrt{n}) \rho_{j,n}^0 U_j(u/\sqrt{n})^*,
\]

with \( U_j(u) \) as above. Finally, we define the vectors

\[
|j, w\rangle := U_j(w)|j, j\rangle \tag{4.11}
\]

which will be used in later computations, and notice that their coordinates with respect to the \(|j, m\rangle\) basis are given by \( 24 \):

\[
|j, m| j, w\rangle = \sqrt{\frac{2j}{j+m}} \zeta^{j-m}(1 - |\zeta|^2)^{j+m}. \tag{4.12}
\]

where \( \zeta = e^{i\varphi_w} \sin |w| \) with \( \varphi_w = \text{Arg}(-w_y + iw_x) \).

5. CONSTRUCTION OF THE CHANNELS

For each irreducible representation space \( \mathcal{H}_j \) we define the isometry \( V_j : \mathcal{H}_j \to L^2(\mathbb{R}) \) by

\[
V_j : |j, m\rangle \mapsto |j - m\rangle \tag{5.1}
\]

where \( \{ |n\rangle, n \geq 0 \} \) represents the energy eigenbasis of the quantum oscillator with eigenfunctions \( \psi_n(x) = H_n(x)e^{-x^2/2}/\sqrt{\pi 2^n n!} \in L^2(\mathbb{R}) \). Using the decomposition \( 4.9 \) we put together the different blocks we construct for each \( n \in \mathbb{N} \) the “global” isometry

\[
V_n := \bigoplus_{j=0,1/2}^{n/2} V_j \otimes 1 : \bigoplus_{j=0,1/2}^{n/2} \mathcal{H}_j \otimes \mathbb{C}^{n_j} \to L^2(\mathbb{R}) \otimes \mathcal{K}_n,
\]

where \( \mathcal{K}_n := \bigoplus_{j=0,1/2}^{n/2} \mathbb{C}^{n_j} \). By tracing over \( \mathcal{K}_n \) we obtain the channel \( T_n(\rho) := \text{Tr}_{\mathcal{K}_n}(V_n \rho V_n^*) \) mapping a joint state of \( n \) spins into a state of the quantum oscillator. This channel satisfies the convergence condition \( 4.4 \) as shown by the estimate

\[
\|T_n(\rho_n^u) - \phi^u\|_1 \leq \sum_{j=0,1/2}^{n/2} p_n(j) \|V_j \rho_{j,n}^u V_j^* - \phi^u\|_1 \leq 2 \sum_{j \notin \mathcal{J}_{n,e}} p_n(j) + \sup_{u \in I^2} \max_{j \in \mathcal{J}_{n,e}} \|V_j \rho_{j,n}^u V_j^* - \phi^u\|_1,
\]

where the first term on the right side converges to 0 by \( 4.10 \), and for the second one we apply the following Proposition \( 5.1 \) which is the major technical contribution of this paper.

Proposition 5.1 The following uniform convergence holds

\[
\lim_{n \to \infty} \sup_{u \in I^2} \max_{j \in \mathcal{J}_{n,e}} \|V_j \rho_{j,n}^u V_j^* - \phi^u\|_1 = 0.
\]

where \( \mathcal{J}_{n,e} \) is the set defined above equation \( 4.10 \).

The proof of the Proposition requires a few ingredients which in our opinion are important on their own for which reason we formulate them apart and refer to relevant papers for the proofs.

Theorem 5.2 \( 39 \) Let \( a, b \in M(\mathbb{C}^d) \), satisfying \( \text{Tr}(a) = \text{Tr}(b) = 0 \) and define

\[
L(a, b) = \exp(ia) \exp(ib) - \exp(ia + ib) \exp\left(\frac{1}{2} [a, b]\right).
\]

On \( (\mathbb{C}^2)^\otimes n \) we define the fluctuation operator

\[
F_n(a) = \frac{1}{\sqrt{n}} \sum_{j=0}^{n/2} a_j,
\]

where \( a_j = 1 \otimes \cdots \otimes a \otimes \cdots \otimes 1 \) with a acting on the i’s position of the tensor product. Notice that \( \exp(iF_n(a)) = \exp(ia/\sqrt{n})^\otimes n \) and \( \sqrt{n}[F_n(a), F_n(b)] = F_n([a, b]) \). Then

\[
\lim_{n \to \infty} \|L(F_n(a), F_n(b))\| = 0.
\]

The convergence is uniform over \( \|a\|, \|b\| \leq C \) for some constant \( C \).

This Theorem is a key ingredient of the quantum central limit Theorem \( 36 \) and it is not surprising that it plays an important role in our quantum local asymptotic normality result which is an extension of the latter. We apply the Theorem to two unitaries of the form \( U(u/\sqrt{n})^\otimes n = \exp\left(i(u_x a_x + u_y a_y)\right)/\sqrt{n}\)^\otimes n \). We thus get information on the effect of the \( U_j(u/\sqrt{n}) \) on the highest weight vectors \(|j, j\rangle\) of an irreducible representation.

Corollary 5.3 For any unitary \( U \) and state \( \tau \) let \( \text{Ad}[U](\tau) := \tau U^* \) and consider the rotated states

\[
\tau(u, v, j, n) := \text{Ad} \left[ U_j \left( \frac{u}{\sqrt{n}} \right) U_j \left( \frac{v}{\sqrt{n}} \right) \right] (|jj\rangle\langle jj|);
\]

\[
\tau(u + v, j, n) := \text{Ad} \left[ U_j \left( \frac{u + v}{\sqrt{n}} \right) \right] (|jj\rangle\langle jj|).
\]

Then the following uniform convergence holds

\[
\lim_{n \to \infty} \sup_{u, v, w \in I^2} \sup_{j \in \mathcal{J}_{n,e}} \|\tau(u, v, j, n) - \tau(u + v, j, n)\|_1 = 0.
\]

Proof: By applying Theorem 5.2 to \( U(u/\sqrt{n})^\otimes n \) and \( U(v/\sqrt{n})^\otimes n \), the first term of \( L(F_n(a)) \) is

\[
U_1 = U \left( \frac{u}{\sqrt{n}} \right)^\otimes n U \left( \frac{v}{\sqrt{n}} \right)^\otimes n,
\]
and the second is
\[ U_2 = U \left( \frac{u + v}{\sqrt{n}} \right)^n \exp \left( \frac{F_u(u,v)}{2\sqrt{n}} \right) \]

with
\[ [u, v] := [u_x \sigma_x + u_y \sigma_y, v_x \sigma_x + v_y \sigma_y] = 2(u_x v_y - u_y v_x)\sigma_z. \]

The norm one distance between these two operators is going to 0 as \( n \) is going to infinity, uniformly on \((u, v) \in I^2\). We may apply these operators on any pure state of \((\mathbb{C}^2)^\otimes_n\), in particular on \([j, j](j, j)\) for any \( j \in J_{n, e} \) after block-diagonalization and preserve the uniform limit
\[ \| \text{Ad}[U_1](\langle jj \rangle_{(jj)}) - \text{Ad}[U_2](\langle jj \rangle_{(jj)}) \| \to 0, \quad n \to \infty. \] (5.2)

Now the action of \( \exp \left( \frac{\rho_n(u,v)}{2\sqrt{n}} \right) \) on \([j, j](j, j)\] is simply identity because \([jj]\) is an eigenvector of \( J_{j, z} \). Therefore
\[ \text{Ad}[U_2]\langle jj \rangle_{(jj)} = \tau(u + v, j, n). \]

Togther with (5.2), this ends the proof. \( \square \)

The following Lemma is a slight strengthening of a theorem by Hayashi and Matsumoto [29].

**Lemma 5.4** The uniform convergence holds
\[ \limsup_{n \to \infty} \sup_{u \in I^2} \| V_{j, n}^* \rho_n^u V_{j, n}^\ast - \phi^0 \|_1 = 0, \]
where \( |z\) denotes a coherent state of the oscillator, and \( \alpha_u := (-u_y + iu_x) \). Moreover for any sequence \( j_n \to \infty \) we have
\[ \lim_{n \to \infty} \| V_{j_n} \rho_n^0 V_{j_n}^* - \phi^0 \|_1 = 0. \] (5.3)

The convergence holds uniformly over all sequences \( j_n \) such that \( j_n/n > c \) for some fixed constant \( c > 0 \), so in particular for \( j_n \in J_{n, e} \).

**Proof.** We first prove the easier relation (5.3). As both density matrices are diagonal we get
\[ \| V_{j_n} \rho_n^0 V_{j_n}^* - \phi^0 \|_1 = \frac{(1 - p)p^{2j_n + 1}}{1 - p^{2j_n + 1}} \sum_{k=0}^{2j_n} p^k - (1 - p) \sum_{k=2j_n + 1}^{\infty} p^k \leq \frac{p^{2j_n + 1}}{1 - p^{2j_n + 1}} + p^{2j_n + 1} \to 0, \]
as \( n \to \infty \).

As for the first relation, let us denote \( |u, j, n\rangle := V_{j, n}^\ast \left( \frac{u}{\sqrt{n}} \right)(j, j) \), then by (4.12) and (5.1) we have
\[ \langle k|u, j, n\rangle = \sqrt{\frac{2j}{k}} \sin(|u|/\sqrt{n})e^{i\phi}\cos(|u|/\sqrt{n})^{2j-k}. \]

Now, the following asymptotical relations hold uniformly over \( j \in J_{n, e} \):
\[ \sin \left( \frac{|u|}{\sqrt{n}} \right)^k = \left( \frac{|u|}{\sqrt{n}} \right)^k \left( 1 + O(|u|^2 n^{-1}) \right), \]
\[ \cos \left( \frac{|u|}{\sqrt{n}} \right)^{2j-k} = \exp \left( \frac{-2(j - 1)|u|^2}{2} \right) \left( 1 + O(|u|^2 n^{-1}) \right), \]
\[ \frac{2j}{k} = \frac{((j - 1)n)^k}{k!} \left( 1 + O(n^{-1}) \right), \]
and thus the coefficients converge uniformly to those of the corresponding coherent states as \( n \to \infty \).
\[ \langle k|u, j, n\rangle \to \exp \left( \frac{-2(j - 1)|u|^2}{2} \right) \left( e^{i\phi}|u|\sqrt{2j - 1} \right). \] (5.4)

**Proof of Proposition 5.3.** The main idea is to notice that \( \phi^0 \) is a thermal equilibrium state of the oscillator and can be generated as a mixture of coherent states with centered Gaussian distribution over the displacements:
\[ \phi^0 = \frac{1}{2\pi s^2} \int e^{-|z|^2/2s^2} |z\rangle \langle z| d^2z. \] (5.4)

The easiest way to see this is to think of the oscillator states in terms of their Wigner functions. Indeed, the Wigner function of a coherent state is
\[ \rho_{z}(q, p) = \exp \left( -(q - \sqrt{2} \Re z)^2 - (p - \sqrt{2} \Im z)^2 \right), \]
and thus the state given by (5.3) has Wigner function which is the convolution of two centered Gaussians which is again a centered Gaussian with variance equal to the sum of their variances \( 2s^2 + 1/2 \) which is equal to the variance of \( \phi^0 \) for \( s^2 := p/(2(1 - p)) \). Similarly,
\[ \phi^u = \frac{1}{2\pi s^2} \int e^{-|z|^2 - 2\Im z|z|^2/2s^2} |z\rangle \langle z| d^2z. \] (5.5)

Let us first remark that
\[ \| V_{j_n} \rho_n^u V_{j_n}^* - \phi^u \|_1 \leq \| \rho_n^u - V_{j_n}^* \phi^0 V_{j_n} \|_1 + \| \phi^0 - P_{j_n} \phi^u P_{j_n} \|_1, \]
where \( P_{j_n} = V_{j_n}^\ast V_{j_n} \) is the projection onto the image of \( V_{j_n} \), and
\[ \lim_{n \to \infty} \sup \sup_{u \in I^2} \| \phi^u - P_{j_n} \phi^u P_{j_n} \|_1 = 0, \]
because \( j_n \to \infty \) uniformly and \( P_{j_n} \) converges to the identity in strong operator topology (a tightness property). Thus it is enough to show that
\[ \lim_{n \to \infty} \sup \sup_{u \in I^2} \| \rho_n^u - V_{j_n}^* \phi^0 V_{j_n} \|_1 = 0. \]
Now
\[
\|\rho_{j_n}^u - V_{j_n}^* \phi^u V_{j_n}\|_1 = \| \text{Ad} \left[ U_{j_n} \left( \frac{u}{\sqrt{n}} \right) \right] (\rho_0^u) - V_{j_n}^* \phi^u V_{j_n}\|_1 \leq \| \rho_0^u - V_{j_n}^* \phi^0 V_{j_n}\|_1 + \| \text{Ad} \left[ U_{j_n} \left( \frac{u}{\sqrt{n}} \right) \right] (V_{j_n}^* \phi^0 V_{j_n} - V_{j_n}^* \phi^u V_{j_n})\|_1.
\]

The first term on the right side of the inequality converges to zero by Lemma 5.4 uniformly for any sequence \((j_n)\) such that \(j_n \in \mathcal{J}_{n,e}\) and does not depend on \(u\). Using 5.4 and 5.5 we bound the second term by

\[
\frac{1}{s \sqrt{2\pi}} \int e^{-|z|^2/2s^2} \| \Delta(u, z, j_n)\|_1 d^2z
\]

where the operator \(\Delta(u, z, j_n)\) is given by

\[
\Delta(u, z, j_n) := \text{Ad} \left[ U_{j_n} \left( \frac{u}{\sqrt{n}} \right) \right] (V_{j_n}^* |z\rangle \langle z| V_{j_n}) - V_{j_n}^* |z + \sqrt{2\mu - 1\alpha_u}\rangle \langle z + \sqrt{2\mu - 1\alpha_u}| V_{j_n}
\]

We analyze the expression under the integral. Let \(z \in \mathbb{R}^2\) be such that \(\alpha_u = z/\sqrt{2\mu - 1}\), then

\[
\| \text{Ad} \left[ U_{j_n} \left( \frac{u}{\sqrt{n}} \right) \right] (V_{j_n}^* |z\rangle \langle z| V_{j_n}) - V_{j_n}^* |z + 2\mu - 1\alpha_u\rangle \langle z + 2\mu - 1\alpha_u| V_{j_n}\|_1
\]

By Corollary 5.3 the first term on the right side converges to zero uniformly in \((u, j_n) \in I^2 \times \mathcal{J}_{n,e}\). By Lemma 5.3 we have that the last two terms converge to zero uniformly in \((u, j_n) \in I^2 \times \mathcal{J}_{n,e}\). Thus if we denote

\[
F_n(z) := \sup_{j_n \in \mathcal{J}_{n,e}} \sup_{u \in I^2} \| \Delta(u, z, j_n)\|_1
\]

then \(0 \leq F_n(z) \leq 2\), \(\lim_{n \to \infty} F_n(z) = 0\) for all \(z \in \mathbb{R}^2\), and by the Lebesgue dominated convergence theorem we get

\[
\lim_{n \to \infty} \frac{1}{n^{1/2}} \int e^{-|z|^2/2s^2} F_n(z) d^2z = 0.
\]

This implies the statement of the Proposition 5.3.

6. CONSTRUCTION OF THE INVERSE CHANNEL \(S_n\)

To complete our proof of asymptotic equivalence as defined by 6.4, we must now exhibit the inverse channel \(S_n\) which maps the displaced thermal states \(\phi^u\) of the oscillator into approximations of the rotated spin states. As the latter are block diagonal with weights \(p_n(j)\) as defined in equation 6.7, it is natural to look for \(S_n\) of the form

\[
S_n(\phi) = \bigoplus_{j=0,1,2} p_n(j) S_n^j(\phi) \otimes \frac{1}{n_j}
\]

where \(S_n^j\) are channels with outputs in \(\mathcal{H}_j\). Moreover because \(V_j : \mathcal{H}_j \to L^2(\mathbb{R})\) is an isometry we can choose \(S_n^j\) such that

\[
S_n^j (V_j \rho V_j^*) = \rho,
\]

for all density matrices \(\rho\) on \(\mathcal{H}_j\). This property does not fix the channel completely but it is sufficient for our purposes. Basically what we want is an inverse of the embedding \(V_j : V_j^*\) used for the direct channel and one way to get this is as follows First block diagonalize \(\phi\) to get \(P_j \phi P_j^* + P_j^\perp \phi P_j^\perp\) where \(P_j\) is the projection onto the image of \(V_j\), i.e. \(P_j = V_j V_j^*\), and note that this is a trace preserving completely positive map. This block diagonal state can be now seen as a state on the direct sum algebra \(\mathcal{B}(P_j L^2(\mathbb{R})) \oplus \mathcal{B}(P_j^\perp L^2(\mathbb{R}))\) and can be mapped to a state on \(\mathcal{B}(\mathcal{H}_j)\) by the channel \(V_j^* \cdot V_j \oplus S_j^\perp\) with \(S_j^\perp\) arbitrary on the ‘upper block’. The resulting composition is the channel \(S_n^j\) satisfying property 6.1.

Theorem 6.1 The following holds

\[
\lim_{n \to \infty} \sup_{u \in I^2} \| S_n(\phi^u) - \rho_u^u \|_1 = 0.
\]
Proof. As both \( \rho_n^{u} \) and \( S_n(\phi^n) \) are block-diagonal we may decompose their distance as

\[
\| S_n(\phi^n) - \rho_n^{u} \|_1 = \sum_{j=0}^{n/2} p_n(j) \| S_n^j(\phi^n) - \rho_n^{u,j} \|_1 \\
\leq \sum_{j \in J_{n,x}} 2p_n(j) + \sum_{j \in J_{n,x}} p_n(j) \| S_n^j(\phi^n) - S_n^j (V_j \rho_n^{u,j} V_j^*) \|_1 \\
+ \sum_{j \in J_{n,x}} p_n(j) \| S_n^j(\phi^n) - \rho_n^{u,j} \|_1 \\
\leq 2 \sum_{j \in J_{n,x}} p_n(j) + \sum_{j \in J_{n,x}} p_n(j) \| \phi^n - V_j \rho_n^{u,j} V_j^* \|_1,
\]

where we have used at the last line that \( S_n^j \) is a contraction and property (6.1) of \( S_n^j \). Now the first sum is going to 0 by (1.10) and the second sum is also uniformly going to 0 by use of Proposition 5.1.

\[ \square \]

7. APPLICATIONS

A. The optimal Bayes measurement is also asymptotically local minimax

In this subsection we will introduce some ideas from the pointwise approach to state estimation. We show that the measurement which is known to be optimal for a uniform prior in the Bayesian set-up, is also asymptotically optimal in the pointwise sense.

Using the jargon of mathematical statistics, we will call quantum statistical experiment (model) \( \{ \rho^\theta \in M(\mathbb{C}^d) : \theta \in \Theta \} \) a family of density matrices indexed by a parameter belonging to a set \( \Theta \). The main examples of quantum statistical experiments considered so far are that of identical qubits

\[
\mathcal{F} := \{ \rho^{\otimes n} : \rho \in M(\mathbb{C}^2) \},
\]
the local model

\[
\mathcal{F}^I := \{ \rho_n^{u} = (\rho^{u^{1/\sqrt{n}}} \otimes_n, u \in I^2 \},
\]
and its “limit” model

\[
\mathcal{G}^I := \{ \phi^n, u \in I^2 \},
\]
where \( I = [-a, a] \), and \( \rho_n^{u} \) and \( \phi^n \) are defined by (1.1) and (1.2). More generally we can replace the square \( I^2 \) by an arbitrary region \( K \) in the parameter space and obtain:

\[
\mathcal{G}^K := \{ \phi^n, u \in K \subset \mathbb{R}^2 \}.
\]

We shall also make use of

\[
\mathcal{G} := \{ \phi^n, u \in \mathbb{R}^2 \}.
\]

A natural choice of distance between density matrices is related to the fidelity square

\[
F(\rho, \sigma)^2 = \left[ \text{Tr} \left( (\sqrt{\rho} \sigma \sqrt{\rho})^{1/2} \right) \right]^2,
\]
which is locally quadratic in first order approximation, i.e.

\[
1 - F(\rho_n^{u}, \rho_n^{\nu})^2 \approx \frac{1}{n} \| u - v \|^2.
\]

As we expect that reasonable estimators are in a local neighborhood of the true state we will replace the fidelity square by the local distance

\[
d(u, \hat{u}) = \| \hat{u} - u \|^2.
\]

and define the risk of a measurement-estimator pair as \( R_M(u, \hat{u}) = \langle d(u, \hat{u}) \rangle \), keeping in mind the factor 1/n relating the risks expressed in local and global parameters.

Similarly to the Bayesian approach, we are interested in estimators which have small risk everywhere in the parameter space and we define a worst case figure of merit called minimax risk.

Definition 7.1 The minimax risk of a quantum statistical experiment \( \mathcal{E} \) over the parameter space \( \Theta \) for loss function \( d(\theta, \hat{\theta}) \), is defined as

\[
C(\mathcal{E}) = \inf_{M, \hat{\theta}} \sup_{\theta} R_M(\theta, \hat{\theta}).
\]

where the infimum is taken over all measurement-estimator pairs \( (M, \hat{\theta}) \), and \( R_M(\theta, \hat{\theta}) = \langle d(\theta, \hat{\theta}) \rangle \).

The minimax risk tells us how difficult is the model and thus we expect that if two models are “close” to each other then their minimax risks are almost equal. The “statistical distance” between quantum experiments is defined in a natural way with direct physical interpretation and such a problem has been already addressed in (b) for the case of a quantum statistical experiment consisting of a finite family of pure states.

Definition 7.2 Let \( \mathcal{E} = \{ \rho^\theta \in M(\mathbb{C}^d) : \theta \in \Theta \} \) and \( \mathcal{F} = \{ \tau^\theta \in M(\mathbb{C}^d) : \theta \in \Theta \} \) be two quantum statistical experiments (models) with the same parameter space \( \Theta \). We define the deficiencies

\[
\delta(\mathcal{E}, \mathcal{F}) = \inf_{T} \sup_{\theta \in \Theta} \| T(\rho^\theta) - \tau^\theta \|_1,
\]

\[
\delta(\mathcal{F}, \mathcal{E}) = \inf_{S} \sup_{\theta \in \Theta} \| \rho^\theta - S(\tau^\theta) \|_1,
\]

where the infimum is taken over all trace preserving channels \( T : M(\mathbb{C}^d) \to M(\mathbb{C}^d) \) and \( S : M(\mathbb{C}^d) \to M(\mathbb{C}^d) \).

With this terminology, our main result states that for any bounded interval \( I \):

\[
\lim_{n \to \infty} \max \left( \delta(\mathcal{F}^I_n, \mathcal{G}^I), \delta(\mathcal{G}^I, \mathcal{F}^I_n) \right) = 0. \quad (7.2)
\]
As suggested above, the deficiency has a direct statistical interpretation: if we want to estimate \( \theta \) in both statistical experiments \( \mathcal{E} \) and \( \mathcal{F} \) and we choose a bounded loss function \( d(\theta, \hat{\theta}) \leq K \) then for any measurement and estimator \( \hat{\theta} \) for \( \mathcal{F} \) with risk \( R_M(\theta, \hat{\theta}) = \langle d(\theta, \hat{\theta}) \rangle \) we can find a measurement \( N \) on \( \mathcal{E} \) whose risk is at most \( R_M(\theta, \hat{\theta}) + K \delta(\mathcal{E}, \mathcal{F}) \). Indeed if we choose \( T \) such that the infimum in the definition of \( \delta(\mathcal{E}, \mathcal{F}) \) is achieved, we can map the state \( \rho^a \) through the channel \( T \) and then perform \( M \) to obtain an estimator \( \hat{\theta} \) for which

\[
R_N(\theta, \hat{\theta}) = \langle d(\theta, \hat{\theta}) \rangle = \int d(\theta, \hat{\theta}) \text{Tr} \left( T(\rho^a) M(\hat{d}) \right) \leq \int d(\theta, \hat{\theta}) \text{Tr} \left( \rho^a \right) + \|d\|_{\infty} \|T(\rho^a) - \rho^a\|_1 \leq R_M(\theta, \hat{\theta}) + K \delta(\mathcal{E}, \mathcal{F}).
\]

This means that the difficulty of estimating the parameter \( \theta \) in the two models is comparable within a factor \( \delta(\mathcal{E}, \mathcal{F}) \). With the above definition of the minimax risk and using the convergence (2) we obtain the following lemma.

**Lemma 7.3** Let \( I = [-a, a] \) with \( 0 < a < \infty \), then

\[
\lim_{n \to \infty} C(\mathcal{F}_n^I) = C(G^I).
\]

The minimax risk for the local family \( \mathcal{F}_n^I \) is a figure of merit for the “local difficulty” of the global model \( \mathcal{F}_n \). It converges asymptotically to the minimax risk of a family of thermal states. However this quantity depends on the arbitrary parameter \( I = [-a, a] \) which we would like to remove as our last step in defining the local asymptotic minimax risk:

\[
C_{\text{a.m.}}(\mathcal{F}_n : n \in \mathbb{N}) := \lim_{a \to \infty} \lim_{n \to \infty} C(\mathcal{F}_n^I) = \lim_{a \to \infty} C(G^I).
\]

This quantity depends in principle on the state which is at the center of the local neighborhood. However by invariance under rotations, the risk is constant for a given pair of eigenvalues of the density matrix. Now, as one might expect the minimax risks for the restricted families of thermal states will converge to that of the experiment with no restrictions on the parameters. The proof of this fact is however non-trivial.

**Lemma 7.4** Let \( I = [-a, a] \), then we have

\[
\lim_{a \to \infty} C(G^I) = C(G)
\]

Moreover the heterodyne measurement saturates \( C(G) \), and thus \( C(G) \) is equal to the Holevo bound.

**Proof.** The inequality in one direction is easy. For any estimator, \( \sup_{u \in \mathbb{R}^2} R_M(u, \hat{u}) \leq \sup_{u \in \mathbb{R}^2} R_M(u, \hat{u}) \), so that \( C(G^I) \leq C(G) \) and the same holds for the limit. By the same reasoning, for any \( K_1 \subset K_2 \subset \mathbb{R}^2 \) we have \( C(G^{K_1}) \leq C(G^{K_2}) \).

When calculating minimax bounds we are interested in the worst risk of estimators within some parameter region \( K \), and this worst risk is obviously higher than the Bayes risk with respect to the probability distribution with constant density on \( K \). We shall work on \( B(0, c + b) \) the ball of center 0 and radius \( (c + b) \), with \( b > c \), and denote our measurement \( M \) with density \( m(u)du \). In general \( M \) need not have a density, but this will ease notations. Then

\[
\sup_{u \in B(0, c + b)} R_M(u, \hat{u}) \geq \int_{B(0, c + b) \times \mathbb{R}^2} \frac{du \; \hat{u}}{\pi(c + b)^2} \|u - \hat{u}\|^2 \text{Tr} (\rho^u m(\hat{u})).
\]

We fix the following notations

\[
f(D) = \int_D \; d\hat{u} \; ||x - \hat{u}||^2 \text{Tr}(\rho^u m(\hat{u})),
g(D) = \int_D \; d\nu \text{Tr}(\rho^u m(\nu)),
\]

and define the domains

\[
D_1 = \{ (u, \hat{u}) | u \in B(0, c + b), \hat{u} \in \mathbb{R}^2 \},
D_2 = \{ (u + k, k) | u \in B(0, c), k \in B(0, b) \},
D_3 = \{ (u, u + h) | u \in B(0, b - c), h \in B(0, c) \},
D_4 = \{ (u, u + h) | u \in B(0, b - c), h \in \mathbb{R}^2 \setminus B(0, c) \}.
\]

Notice the following relations:

\[
D_3 \subset D_2 \subset D_1, \quad D_4 \subset D_1 \setminus D_2.
\]

Then (3) can be rewritten as

\[
\sup_{u \in B(0, c + b)} R_M(u, \hat{u}) \geq \frac{1}{\pi(c + b)^2} f(D_1).
\]

The following inequalities follow directly from the definitions:

\[
f(D_2) \leq c^2 g(D_2) \quad f(D_3) \leq c^2 g(D_3)
\]

\[
f(D_4) \geq c^2 g(D_4) \quad g(D_4) + g(D_3) = \pi(b - c)^2.
\]

Using these and (4), we may write:

\[
\frac{1}{\pi(c + b)^2} f(D_1) \geq \frac{1}{\pi(c + b)^2} (f(D_2) + f(D_4))
\]

\[
\geq \frac{1}{\pi(c + b)^2} (f(D_2) + c^2 g(D_4))
\]

\[
= \frac{(b - c)^2}{\pi(b - c)^2} \left( \frac{f(D_2)}{g(D_2)} - c^2 \frac{g(D_3)}{\pi(b - c)^2} \right)
\]

\[
\geq \frac{(b - c)^2}{\pi(b - c)^2} \left( \frac{f(D_2)}{g(D_2)} - c^2 \right)
\]

\[
= \frac{(b - c)^2}{\pi(b + c)^2} \left( \frac{f(D_2)}{g(D_2)} - c^2 \right)
\]

\[
\geq \frac{(b - c)^2}{\pi(b + c)^2} \left( \frac{f(D_2)}{g(D_2)} - c^2 \right).
\]
We analyze now the expression \( f(D_2)/g(D_2) \). By using the definition of the displaced thermal states \( \phi^u \) we get that \( \text{Tr} \left[ \phi^{u+k}m_1(l) \right] = \text{Tr} \left[ \phi^km_u(l) \right] \), where
\[
m_u(l) := D(-\sqrt{2\mu - 1}a_u)m(l)D(-\sqrt{2\mu - 1}a_u).
\]

Then
\[
g(D_2) = \int_{B(0,c)\times B(0,b)} duds r \left[ \phi^{u+k}m(k) \right] = \text{Tr} \left[ \phi_c \tilde{m}_b \right],
\]
where we have written
\[
\phi_c = \int_{B(0,c)} \phi^u du, \quad \tilde{m}_b = \int_{B(0,b)} m_k(k)dk.
\]

Upon writing \( v_c := \int_{B(0,c)} ||u||^2 \phi^u du \), we get similarly \( f(D_2) = \text{Tr} [v_c \tilde{m}_b] \). Note that by rotational symmetry \( v_c \) and \( \phi_c \) are diagonal in the number operator eigenbasis, so without restricting the generality we may assume that \( \tilde{m}_b \) is also diagonal in that basis: \( \tilde{m}_b = \sum_k p_k[k] \langle k | k \rangle \). We have then
\[
\frac{f(D_2)}{g(D_2)} = \frac{\sum_{k \in \mathbb{N}} p_k[k] v_c[k]}{\sum_{k \in \mathbb{N}} p_k[k] \phi_c[k]} \geq \inf_{k \in \mathbb{N}} \frac{\langle k | v_c[k] \rangle}{\langle k | \phi_c[k] \rangle}.
\]
The infimum on the right side is achieved by the vacuum vector. By Lemma 7.5, this fact follows from the inequality
\[
\frac{\langle k | \phi^u_1 | k \rangle}{\langle k | \phi^u_2 | k \rangle} \geq \frac{\langle 0 | \phi^u_1 | 0 \rangle}{\langle 0 | \phi^u_2 | 0 \rangle}, \quad ||u_1|| \geq ||u_2||,
\]
which can be checked by explicit calculations.

Letting now \( c \) and \( b \) go to infinity with \( c = o(b) \) and using Proposition 7.6, we obtain that
\[
\lim_{n \to \infty} C(G_n) \geq \int_{B(0,\sqrt{n})} ||u||^2 du,
\]
which is exactly the pointwise risk of the heterodyne measurement \( H(du) = h(u)du \) whose density is
\[
h(u) = (2\mu - 1)D(-\sqrt{2\mu - 1}a_u)|0\rangle\langle 0|D(-\sqrt{2\mu - 1}a_u).
\]

By symmetry this pointwise risk does not depend on the point, so that \( C(G) \leq R_H(u, \hat{u}) \). And we have our second inequality: \( \lim_{n \to \infty} C(G_n) \geq C(G) \).

Moreover, the heterodyne measurement is known to saturate the Holevo bound for \( G = Id \) and the Cramér-Rao bound for locally unbiased estimators. We conclude that the local minimax risk for qubits is equal to the minimax risk for the limit Gaussian quantum experiment which is achieved by the heterodyne measurement.

\[\square\]

**Lemma 7.5** Let \( p \) and \( q \) be two probability densities on \([0,1]\) and assume that
\[
\frac{p(x_1)}{p(x_2)} \geq \frac{q(x_1)}{q(x_2)}, \quad x_1 \geq x_2.
\]
Then \( \int x^2p(x)dx \geq \int x^2q(x)dx \).

**Proof.** It is enough to show that there exists a point \( x_0 \in [0,1] \) such that \( p(x) \leq q(x) \) for \( x \leq x_0 \) and \( p(x) \geq q(x) \) for \( x \geq x_0 \). Now, if \( p(x) \leq q(x) \) then by using the assumption we get that \( p(y) \leq q(y) \) for all \( y \leq x \). Similarly, if \( p(x) \geq q(x) \) then \( p(y) \leq q(y) \) for all \( y \geq x \). This implies the existence of the crossing point \( x_0 \).

By putting the last two lemmas together we obtain the following.

**Proposition 7.6** The local asymptotic minimax risk \( C_{l.a.m.}(F_n) : n \in \mathbb{N} \) for the qubit state estimation problem is equal to the minimax risk \( C(G) \) for the corresponding quantum Gaussian shift experiment which is achieved by the heterodyne measurement.

The natural question is now the following: is there a sequence of measurement-estimator pairs for the qubits which achieves this the risk \( C_{l.a.m.}(F_n) : n \in \mathbb{N} \) asymptotically for all local neighborhoods simultaneously, i.e. without prior knowledge of the center \( \rho^0 \) of the \( 1/\sqrt{n} \) ball within which the true state lies. Intuitively, the following procedure seems natural: use the local asymptotic normality to transfer the heterodyne measurement from the space of the oscillator to that of the qubits and in this way achieve the desired asymptotic risk. However this requires the knowledge of the local neighborhood on which the convergence holds. In order to obtain this information about the state we need to ‘localize’ the state by performing a first stage of (rough) measurements on a small proportion of the systems of order \( o(n) \) and then perform the (optimal) heterodyne type measurements corresponding to the local neighborhood of the first stage estimator. In order to make this argument rigorous we need some finer estimates on the region in which local asymptotic normality holds and we leave this problem for a separate work.

However, there exists another measurement which achieves the risk \( C_{l.a.m.}(F_n) : n \in \mathbb{N} \), namely the optimal measurement from the Bayesian point of view discussed in [24][20]. The connection between the local and Bayesian approaches is discussed in more details in the next Subsection to which we refer for the appropriate definitions. In particular, the next proposition can be better understood after reading the next Subsection but we state it here because it is a direct consequence of the results derived in this Subsection.

Let us denote by \((M_n, \hat{\rho}_n)\) the measurement-estimator pair from [21][20] which are optimal from the Bayesian point of view.

**Proposition 7.7** The optimal measurement-estimator pair \((M_n, \hat{\rho}_n)\) in the Bayesian setup is an asymptotically local minimax estimation scheme. That is for any \( \rho \)
\[
\lim_{n \to \infty} nR_{M_n}(\rho, \hat{\rho}_n) = C_{l.a.m.}(F_n : n \in \mathbb{N}),
\]
where \( R_{M_n}(\rho, \hat{\rho}_n) \) is the risk with respect to the fidelity distance.
Proof. The pointwise risk of \((M_n, \hat{\rho}_n)\) is known to converge to that of the heterodyne measurement \([21]\). The rest follows from Lemma \([54]\) and Lemma \([54]\). □

B. Local asymptotic equivalence of the optimal Bayesian measurement and the heterodyne measurement

In this subsection we will continue our comparison of the pointwise (local) point of view with the global one used in the Bayesian approach. The result is that the optimal SU(2) covariant measurement \([21, 29]\) converges locally to the optimal measurement for the family of displaced Gaussian states which is a heterodyne measurement \([30]\). Together with the results on the asymptotic local mimimax optimality of this measurement, this closes a circle of ideas relating the different optimality notions and the relations between the optimal measurements.

Let us recall what are the ingredients of the state estimation problem in the Bayesian framework \([24]\). We choose as cost function the fidelity squared \(F(\rho, \sigma)^2 = \text{Tr}(\sqrt{\sqrt{\rho} \sigma \sqrt{\rho}})^2\) and fix a prior prior distribution \(\pi\) over all states in \(\mathbb{C}^2\) which is invariant under the SU(2) symmetry group. Given \(n\) identical systems \(\rho^\otimes n\) we would like to find a measurement \(M_n\) - whose outcome is the estimator \(\hat{\rho}_n\) - which maximizes

\[
R_{\pi, n} := \int \langle F(\hat{\rho}_n, \rho)^2 \rangle \pi(d\rho).
\]

By the SU(2) invariance of \(\pi\), the optimal measurement can be chosen to be SU(2) covariant i.e.

\[
UM_n(d\sigma)U^* = M_n(U^*d\sigma U),
\]

and can be described as follows. First we use the decomposition \([35]\) to make a “which block” measurement and obtain a result \(j\) and the conditional state \(\rho_{j,n}\) as in \([41, 10]\). This part will provide us the eigenvalues of the estimator.

Next we perform block-wise the covariant measurement \(M_{j,n}(d\tilde{s}) = m_{j,n}(\tilde{s})d\tilde{s}\) with

\[
m_{j,n}(\tilde{s}) := (2j + 1)U_j(\tilde{s})^* |j\rangle \langle j| U_j(\tilde{s}) \otimes 1_j
\]

whose result is a unit vector \(\tilde{s}\) where \(U(\tilde{s})\) is a unitary rotating the vector state \(|\tilde{s}\rangle\) to \(|\uparrow\rangle\). The complete estimator is then \(\hat{\rho}_n = \frac{1}{2}(1 + \frac{2j}{\sqrt{n}} \tilde{s} \otimes \tilde{s})\).

We pass now to the description of the heterodyne measurement for the quantum harmonic oscillator. This measurement has outcomes \(u \in \mathbb{R}^2\) and is covariant with respect to the translations induced by the displacement operators \(D(\alpha)\) such that \(H(d\alpha) = h(\alpha) d\alpha\) with

\[
h(\alpha) := (2\mu - 1)D(-\sqrt{2\mu - 1} \alpha) |0\rangle \langle 0| D(\sqrt{2\mu - 1} \alpha).
\]

Using Theorem \([1, 1]\) we can map \(H\) into a measurement on the \(n\)-spin system as follows: first we perform the block step as in the case of the SU(2)-covariant measurements. Then we map \(\rho_{j,n}\) into an oscillator state using the isometry \(V_j\) (see \([31]\)), and subsequently we perform \(H\). The result \(u\) will define our estimator for the local state, i.e.

\[
\hat{\rho}_n = U \left(\frac{u}{\sqrt{n}}\right) \left(\begin{array}{ccc} \frac{1}{2} & \frac{1}{2} & 0 \\ \frac{1}{2} & \frac{1}{2} & -\frac{n}{2} \\ 0 & \frac{n}{2} & 1 \end{array}\right) U^* \left(\frac{u}{\sqrt{n}}\right)^*.
\]

We denote by \(H_n\) the resulting measurement with values in the states on \(\mathbb{C}^2\).

The next Theorem shows that in a local neighborhood of a fixed state \(\rho^0\), the SU(2)-covariant measurement \(M_n\) and the heterodyne type measurement \(H_n\) are asymptotically equivalent in the sense that the probability distributions \(P(M_n, \rho)\) and \(P(H_n, \rho)\) are close to each other uniformly over all local states \(\rho\) such that \(\|\rho - \rho^0\|_1 \leq C/\sqrt{n}\) for a fixed but arbitrary constant \(C < \infty\).

**Theorem 7.8** Let \(\rho^0\) be as in \([41, 1]\), and let

\[
B_n(I) = \{\rho^{\sqrt{n}/|\tilde{\sigma}|} : \tilde{\sigma} \in \mathbb{R}^2\}, \quad |I| < \infty
\]

be a local family of states around \(\rho^0\). Then

\[
\lim_{n \to \infty} \sup_{\rho \in B_n(I)} \| P(M_n, \rho) - P(H_n, \rho) \|_1 = 0
\]

**Proof.** Note first that both \(P(M_n, \rho)\) and \(P(H_n, \rho)\) are distributions over the Bloch sphere and the marginals over the length of the Bloch vectors are identical because by construction the first step of both measurements is the same. Then

\[
\| P(M_n, \rho) - P(H_n, \rho) \|_1 = \sum_j p_n(j) \int |\text{Tr}(\rho_{j,n}(m_{j,n}(\tilde{s}) - h_{j,n}(\tilde{s}))))| d\tilde{s}.
\]

According to \([4, 10]\) we can restrict the summation to the interval \(J_{n, e} \) around \(j = n(\mu - \frac{1}{2})\). By Theorem \([1, 1]\) we can replace (whenever needed) the local states \(\rho_{j,n}^{\sqrt{n}/|\tilde{\sigma}|}\) by their limits in the oscillator space \(\phi^\times\) with an asymptotically vanishing error, uniformly over \(\tilde{\sigma} \in \mathbb{R}^2\).

We make now the change of variable \(\tilde{s} \to u\) where \(u \in \mathbb{R}^2\) belongs to the ball \(|u| < 2\sqrt{n}\pi\), and is the smallest vector such that \(U \left(\frac{u}{\sqrt{n}}\right) = U(\tilde{s})\).

The density of the SU(2) estimator with respect to the measure \(du\) is

\[
m_{j,n}(u) := \frac{2j + 1}{n} U_j \left(\frac{u}{\sqrt{n}}\right)^* |j\rangle \langle j| U_j \left(\frac{u}{\sqrt{n}}\right) J \left(\frac{u}{\sqrt{n}}\right),
\]

where \(J\) is the determinant of a Jacobian related with the change of variables such that \(J(0) = 1\).

Similarly the density of the homodyne-type estimator becomes

\[
h_{j,n}(u) := \sum_{k \in \mathbb{N}} V_{j}^* h \left(\frac{u}{\sqrt{n}}\right) \langle u \rangle |J_{k,n}(u)\rangle.
\]
because displacements in the same direction which differ by multiples of $2\sqrt{n}\pi$ lead to the same unitary on the qubits. Here $J_{k,n}(u)$ is again the determinant of the Jacobian of the map from the $k$-th ring to the disk, in particular $J_{0,n}(u) = 1$.

The integral becomes then
\[
\int_{|u|\leq 2\pi\sqrt{n}} \left| \mathcal{M} \left( \rho_{j,n}(u) - \rho_{j,n}(u) \right) \right| \, du.
\]

We bound this integral by the sum of two terms, the first one being
\[
\int_{|u|\leq 2\pi\sqrt{n}} \left| \mathcal{M} \left( \rho_{j,n}(u) - \rho_{j,n}(u) \right) \right| \, du,
\]

where $\rho_{j,n}(u)$ is just the term with $k = 0$ in $h_{j,n}(u)$. By Lemma 3.2 for any fixed $u$ we have $m_{j,n}(u) \to h(u)$ uniformly over $j \in J_{0,n}$. Using similar estimates as in Lemma 3.2 it can be shown that the function under the integral is bounded by a fixed integrable function $g(u)$ uniformly over $v \in I^2$, and then we can use dominated convergence to conclude that the integral converges to $0$ uniformly over $v \in I^2$ and $j \in J_{0,n}$.

The second term is
\[
\int_{|u|>2\pi\sqrt{n}} \left| \mathcal{M} \left( \rho_{j,n}(u) - \rho_{j,n}(u) \right) \right| \, du,
\]

which is smaller than
\[
\int_{|u|>2\pi\sqrt{n}} \left| \mathcal{M} \left( \rho_{j,n}(u) - \rho_{j,n}(u) \right) \right| \, du,
\]

which converges uniformly to $0$. This can be seen by replacing the states with $\theta^v$ which are “confined” to a fixed region of the size $I^2$ in the phase space, while the terms $h(u)$ are Gaussians located at distance at least $2\pi\sqrt{n}$ from the origin.

Putting these two estimates together we obtain the desired result.

\begin{remark}
The result in the above theorem holds more generally for all states in a local neighborhood of $\rho^0$ but for the proof we need a slightly more general version of Theorem 3.1 where the eigenvalues of the density matrices are not fixed but allowed to vary in a local neighborhood of $(\mu, 1 - \mu)$. This result will be presented in a future work concerning the general case of $d$-dimensional states.
\end{remark}

\section{Discrimination of states}

Another illustration of the local asymptotic normality Theorem is the problem of discriminating between two states $\rho^+ = \rho^+ \rho^0$ when the two states are fixed, this problem has been solved by Helstrom [14], and if we are given $n$ systems in state $\rho^\pm$ then the probability of error converge to $0$ exponentially. Here we consider the problem of distinguishing between two states $\rho^\pm$ which approach each other as $n \to \infty$ with rate $||\rho^\pm - \rho^0||_1 \approx \frac{1}{\sqrt{n}}$. In this case the probability of error does not go to $0$ because the problem becomes more difficult as we have more systems, and converges to the limit problem of distinguishing between two fixed Gaussian states of a quantum oscillator.

This problem is interesting for several reasons. Firstly it shows that the convergence in Theorem 3.1 can be used for finding asymptotically optimal procedures for various statistical problems such as that of parameter estimation and hypothesis testing. Secondly, for any fixed $n$ the optimal discrimination is performed by a rather complicated joint measurement and the hope is that the asymptotic problem of discriminating between two Gaussian states may provide a more realistic measurement which can be implemented in the lab. Thirdly, this example shows that a non-commuting one-parameter families of states is not “classical” as it is sometimes argued, but should be considered as a quantum “resource” which cannot be transformed into a classical one without loss of information. More explicitly, the optimal measurement for estimating the parameter is not optimal for other statistical problems such as the one considered here, and thus different statistical decision problems are accompanied by mutually incompatible optimal measurements.

Let us recall the framework of quantum hypothesis testing for two states $\rho^\pm$: we consider two-outcomes POVM’s $M = (M_-, M_+)$ with $0 \leq M_- \leq 1$ and $M_+ = 1 - M_-$ such that the probability of error when the state is $\rho^\pm$ is given by $\mathcal{R}(M_+ \rho^-)$, and similarly for $\rho^\pm$. As we do not know the state, we want to minimize our worst-case probability error. Our figure of merit (the lower, the better) is therefore:
\[
\mathcal{R}(\rho^+, \rho^-) = \inf_M \{ \mathcal{R}(M_+), \mathcal{R}(M_+) \}
\]

Now we are interested in the case when $\rho^\pm = \rho^\pm \rho^0$ as defined in 3.1, and in the limit $\rho^\pm = \phi^\pm (\mu)$ (recall that both $\rho^\pm$ and $\phi^\pm$ depend on $\mu$). We then have:

\begin{theorem}
The following limit holds
\[
\lim_{n \to \infty} \mathcal{R}(\rho^\pm, \rho^0) = \mathcal{R}(\phi^\pm, \phi^-).
\]
Moreover for pure states this limit is equal to \((1 - (1 - e^{-\gamma\mu}))^{1/2})/2 which is strictly smaller than \(1/2 - er\phi(x)\) which is the limit if we do not use collective measurements on the qubits. Here we have used this convention for the error function: $er\phi(x) = \int_0^x e^{-t^2}/\sqrt{\pi} dt$.
\end{theorem}

\begin{proof}
Let $M$ be the optimal discrimination procedure $\phi^\pm$. Then we use the channel $T_n$ to send $\rho^\pm$ to states of the oscillator and then perform the measurement $M$. By Theorem 3.1 $\|\phi^\pm - T_n(\rho^\pm)\|_1 \to 0$ so that $\mathcal{R}(T_n(\rho^\pm) M_\pm) \to \mathcal{R}(\phi^\pm M_\pm)$. Thus $M \circ T_n$ is asymptotically optimal for $\rho^\pm$.
\end{proof}
Now for pure states $|\psi_+\rangle$ and $|\psi_-\rangle$ the optimal measurement is well-known \cite{15, 16}. It is unique on the span of these pure states and arbitrary on the orthogonal. If we choose the phase such that $\langle \psi_-|\psi_+\rangle > 0$, then $M_+$ is the projector on the vector

$$\frac{|\psi_+\rangle + |\psi_-\rangle}{2\sqrt{1 + \langle \psi_-|\psi_+\rangle}} + \frac{|\psi_+\rangle - |\psi_-\rangle}{2\sqrt{1 - \langle \psi_-|\psi_+\rangle}}$$

and the associated risk is

$$\frac{1}{2}(1 - \sqrt{1 - |\langle \psi_+|\psi_-\rangle|^2})$$

Now in our case, in the limit experiment, $\phi^u$ is the coherent state $|\psi_u\rangle = e^{-|u|^2/2} \sum_n |u|^n/\sqrt{n!} |n\rangle$. So that

$$\langle \psi_u|\psi_{-u}\rangle = e^{-|u|^2} \sum_n \frac{(-|u|^2)^n}{n!} = e^{-2|u|^2},$$

and $R(\phi^u, \phi^{-u}) = \frac{1}{2} \left(1 - \sqrt{1 - e^{-4|x|^2}}\right)$.

We would like to insist here that the best measurement for discrimination is not measuring the positive part of the position observable $Q$ (we assume by symmetry that $\pm u$ is on the first coordinate), as one might expect from the analogy with the classical problem. Indeed if we measure $Q$ then we obtain a classical Gaussian variable with density $p(x) = e^{-(x-u)^2}/\sqrt{\pi}$ and the best guess at the sign $\pm$ has in this case the risk $1/2 - \text{erf}(|u|)$.

This may be a bit surprising considering that measuring $Q$ preserves the quantum Fisher information. The conclusion is simply that the quantum Fisher information is not an exhaustive indicator of the statistical information in a family of states, as it may remain unchanged even when there is a clear degradation in the inference power. This example fits in a more general framework of a theory of quantum statistical experiments and quantum decisions \cite{47}.

\[\square\]

D. Spin squeezed states and continuous time measurements

In an emblematic experiment for the field of quantum filtering and control \cite{37} it is shown how spin squeezed states can be prepared deterministically by using continuous time measurements performed in the environment and real time feedback on the spins. Without going in the details, the basic idea is to describe the evolution of identically prepared spins by passing first to the coherent state picture. There one can easily solve the stochastic Schrödinger equation describing the evolution (quantum trajectory) of the quantum oscillator conditioned on the continuous signal of the measurement device. The solution is a Gaussian state whose center evolves stochastically while one of the quadratures gets more and more squeezed as one obtains more information through the measurement. Using feedback one can then stabilize the center of the state around a fixed point.

This description is of course approximative and holds as long as the errors in identifying the spins with Gaussian states are not significant. The framework developed in the proof of Theorem \cite{14} can then be used to make more precise statements about the validity of the results, including the squeezing process.

Perhaps more interesting for quantum estimation, such measurements may be used to perform optimal estimation of spin states. The idea would be to first localize the state in a small region by performing a weak measurement and then in a second stage one performs a heterodyne type measurement after rotating the spins so that they point approximately in the $z$ direction. We believe that this type of procedure has better chances of being implemented in practice compared with the abstract covariant measurement of \cite{24, 29}.

Acknowledgments

We would like to thank Richard Gill for many discussions and guidance. Mădălina Gută acknowledges the financial support received from the Netherlands Organisation for Scientific Research (NWO).
