ABSTRACT

There is evidence for temperature fluctuations in planetary nebulae and in some Galactic H II regions. If such fluctuations occur in the low-metallicity, extragalactic H II regions used to probe the primordial helium abundance, the derived ³He mass fraction, Yp, could be systematically different from the true primordial value. For cooler, mainly high-metallicity H II regions, the derived helium abundance may be nearly unchanged, but the oxygen abundance could have been seriously underestimated. For hotter, mainly low-metallicity H II regions, the oxygen abundance is likely accurate, but the helium abundance could be underestimated. The net effect is to tilt the Y-versus-Z relation, making it flatter and resulting in a higher inferred Yp. Although this effect could be large, there are no data that allow us to estimate the size of the temperature fluctuations for the extragalactic H II regions. Therefore, we have explored this effect via Monte Carlo simulations of the data in which the abundances derived from a fiducial data set are modified by ∆T chosen from a distribution with 0 ≤ ∆T ≤ ∆T max, where ∆T max is varied from 500 to 4000 K. It is interesting that, although this effect shifts the locations of the H II regions in the Y-versus-O/H plane, it does not introduce any significant additional dispersion.

Subject headings: galaxies: ISM — H II regions — ISM: abundances

1. INTRODUCTION

The primordial abundance of ³He is key to testing the consistency of the standard hot big bang model of cosmology and to using primordial nucleosynthesis as a probe of particle physics (Steigman, Schramm, & Gunn 1977). The availability of large numbers of carefully observed, low-metallicity H II regions has permitted estimates of the primordial helium mass fraction, Yp, whose statistical uncertainties are very small, ≈1% (see Olive & Steigman 1995, hereafter OS; Olive, Steigman, & Skillman 1997, hereafter OSS and references therein, and Olive, Skillman, & Steigman 1997). However, there remains the possibility that in the process of using the observational data to derive the abundances, contamination by unacknowledged systematic uncertainties has biased the inferred value of Yp. Observers have identified many potential sources of systematic uncertainties (Davidson & Kinnan 1985; Pagel et al. 1992, hereafter PSTE; Skillman et al. 1994; Izotov, Thuan, & Lipovetsky 1994, 1997 (ITL); Peimbert 1996) and, where possible, have designed their observing programs to minimize such uncertainties and/or to account for them. It is expected that the contributions from many of the potential sources of systematic uncertainty (if present at all) would vary from H II region to H II region and from observer (telescope/detector combination) to observer, introducing along with a systematic offset in the derived value of Yp an accompanying dispersion in the helium data. More insidious would be systematic errors in, for example, the atomic physics used to convert the observed equivalent widths to abundances, since an offset from the true value of Yp would not be accompanied by an enhanced dispersion in the fits to the data (e.g., Y versus O/H or the weighted mean of Y for the lowest metallicity H II regions; see OSS). In this paper, we explore one potential source of systematic uncertainty in deriving abundances from emission-line data for extragalactic H II regions: temperature fluctuations.

The empirical method to derive chemical abundances in an emitting gas has been used widely since it was first proposed by Peimbert & Costero (1969). The electron density n_e and the gas temperature T are obtained from emission-line intensity ratios and are used to calculate the line emissivity that, along with the observed line intensities, provides the fractional abundance of the ion and, subsequently, the empirical abundance of a given element (see, for example, Osterbrock 1989). In low-density regions, such as those in H II galaxies, the permitted-line emissivities (like those of O, N, and S) are strongly dependent on T, and the dependence on the density may also be important. In H II galaxies, the [S II] line ratio indicates low electron densities (n_e < 500 cm⁻³), and except in those with high temperature, the collisional effects are negligible. Thus, the derived heavy-element abundances depend mainly on a good determination of the temperature. For these regions, the temperature used for the high-ionization lines is that obtained from the [O III] line ratio, T_0,III, while for low-ionization lines, the temperature is derived from T_0,III using results from photoionization models (see, e.g., PSTE).

A similar method is usually applied to planetary nebulae (PN). In contrast to H II regions, for several PNs, the Balmer temperature T_B (obtained from the observed Balmer discontinuity) is also determined. In many cases, T_B is found to be lower than T_0,III (Peimbert 1971; Liu & Danziger 1993). As pointed out by Peimbert (1971), this discrepancy could be due to temperature fluctuations, which, however, are not reproduced by the standard photoionization models for these nebulae (Liu & Danziger 1993). If, indeed, the gas temperature is overestimated by T_0,III, with the true temperature given by T_B, the heavy-element abundances derived from forbidden lines using T_0,III are underestimated (Viegas & Clegg 1994). Indeed, the abnormal chemical abundances inferred for some H II galaxies with W-R fea-

tures may result from just such an overestimate of the gas temperature (Esteban & Peimbert 1995). Although one well-observed giant H II region, NGC 2363, shows just such a discrepancy between the Paschen temperature and $T_{\text{r}}$ in two knots (González-Delgado et al. 1994), temperature fluctuations appear to be absent in the M33 giant H II region NGC 604 (Terlevich et al. 1996). The H II galaxies used to derive the primordial helium abundance are anything but "classical," homogeneous Strömgren spheres; winds from pockets of very hot, young stars may well shock the gas producing temperature fluctuations that, if neglected, would yield an underestimate of the true oxygen abundance. This may introduce a systematic bias into the inferred value of $Y_p$ derived from the $Y$-versus-metallicity correlation. Furthermore, temperature fluctuations will have a direct effect on the helium abundance determined from the recombination lines (Esteban & Peimbert 1995). Although the ratio of He to H emissivities is very nearly independent of temperature, the helium-line intensities are modified from the pure recombination case by collisional excitation (Cox & Daltabuit 1971; Ferland 1986), which is temperature sensitive. When collisions are important, if the "true" H II region temperature has been overestimated, the collisional correction has been overestimated and the "true" helium abundance underestimated. This effect will be largest for the hottest, metal-poor H II regions. When collisions are negligible, it is the temperature dependence of the H and He recombination lines that matters, and $Y_p$ will be slightly overestimated (Peimbert 1995). Thus, the combined effects, which tend to increase the derived oxygen abundance in the metal-rich H II regions and the helium abundance in the metal-poor regions (see Fig. 1), will "tilt" the inferred $Y$-versus-O/H relation, flattening the slope and increasing the intercept, $Y_p$. In this paper we analyze these effects in an attempt to quantify the corresponding systematic uncertainty in $Y_p$.

2. THE METHOD

If the Paschen or Balmer temperatures were available, the corrections described above would be straightforward to implement. Unfortunately, for the low-metallicity, extragalactic H II regions used to derive the primordial abundance of helium, there appears to be no data on the Balmer or Paschen temperatures. To estimate the magnitude of the possible corrections, we have, therefore, adopted a Monte Carlo approach to quantifying the potential systematic uncertainty introduced into the determination of $Y_p$ by uncertainty in the temperature of the H II region gas.

We begin by adopting a fiducial data set using 43 H II galaxies from PSTE, ITL, Skillman & Kennicutt (1993), and Skillman et al. (1994). The role of this fiducial set is merely to provide a comparison, in order to quantify the changes induced by temperature differences. For this reason we have not employed the unpublished data of Skillman et al. (1997; see OS and OSS) nor those H II regions listed in PSTE that they, themselves, did not observe. We follow ITL and eliminate those regions for which their data are noisy or otherwise uncertain. For each H II region in our fiducial data set, we adopt the same algorithms used by these authors to derive the temperature and the fractional abundances in the low-ionization zones. The electron density is obtained from the [S II] line ratio, and we use the Brocklehurst (1972) recombination coefficients for the He and H lines along with the collisional corrections for the He lines from Clegg (1987). The more recent computations of the collisional corrections by Kingdon & Ferland (1995) are in excellent agreement with those of Clegg (1987). The fractional abundance of He$^+$ is the (unweighted) average of the abundances obtained from He I 4471, He I 5876, and He I 6678.

Ignoring any statistical uncertainties, we use these fiducial abundances to find a "standard" linear fit to $Y$ versus O/H (unweighted) in the absence of temperature fluctuations. We emphasize that we are not so much interested in the "best-fit" $Y$-versus-O/H relation for our fiducial data set but, rather the differences in the $Y$-versus-O/H relations between $\Delta T = 0$ and nonzero ($\Delta T = T_{\text{r}} - T$). Figure 1, each point in our data set is shown in the $Y$-versus-O/H plane in the absence of temperature fluctuations ($\Delta T = 0$) and for $\Delta T = 2000$ K, joined by a solid line. As anticipated, the higher metallicity regions tend to be cooler (see Fig. 2). This has the effect that the derived oxygen abundance in high-metallicity regions is very sensitive to temperature fluctuations as is seen clearly in Figure 1.

For planetary nebulae, the observed temperature difference $\Delta T = T_{\text{r}} - T_p$ is typically 2000 K (Lui & Danziger 1993) with one PN having $\Delta T = 6000$ K. For the giant H II region NGC 2363, $\Delta T \geq 3000$ K (González-Delgado et al. 1994). Thus, we have recalculated the helium and oxygen abundances for each H II region with $\Delta T$ chosen from a distribution that ranges from zero to $\Delta T_{\text{r}}$, according to a probability $P(\Delta T)$ to be described below; $\Delta T_{\text{r}}$ is varied in the range $500 \leq \Delta T_{\text{r}} \leq 4000$ K. We repeat this procedure 10,000 times for each choice of $\Delta T_{\text{r}}$. For most H II regions, $Y$ does not decrease with decreasing temperature as might have been expected from the effective recombination coefficients alone (Esteban & Peimbert 1995) provided we account for the collisional effect on the He lines; for H II galaxies with high gas temperature, the collisional effect dominates, leading to an increase of $Y$. As seen in Figure 1, the decrease in $T$ leads to an increase in the oxygen abun-
To probe the sensitivity of our results to the adopted probability distribution of $\Delta T$ values, $P(\Delta T)$, we have considered three simple distributions: flat, linearly increasing, and linearly decreasing. The results for these three different distributions are shown for $\Delta T_{\text{max}} = 4000$ K in Figure 4. Clearly, the effects are closely similar for all choices; in our subsequent discussion (and, in Figs. 3 and 5), we present results for the flat distribution [$P(\Delta T)$ independent of $\Delta T$].

In Figure 5, it is shown how the magnitude of the systematic offsets in slope and intercept scale with $\Delta T_{\text{max}}$. For the not unreasonable choice of $\Delta T_{\text{max}} = 2000$ K, the increase in the inferred value of $Y_p$ is significant, comparable to some estimates of the upper bound to the systematic uncertainty in $Y_p$ (OS; OSS). For larger values of $\Delta T_{\text{max}}$, the systematic offset will be even larger. It might have been anticipated (see OSS) that such large systematic offsets would be accompanied by an increase in the dispersion of the abundances around the best-fit $Y$-versus-$Z$ relation. To test for this, for each realization we have computed $\sigma$, the variance of the residuals between the data ($Y$) and those values predicted by the corresponding fit for that realization ($Y_{\text{fit}}$). However, as seen in Figure 5, for temperature fluctuations, this effect of added dispersion, if present at all, is very small compared, for example, to the typical uncertainty in the individual $\text{H II}$ region $Y$ determinations which are of order 0.010 (OSS). Thus, until there are observations of $\text{H II}$ region temperatures determined from hydrogen lines, it is difficult to set a firm upper bound to the magnitude of the systematic offset in $Y_p$ owing to the possible presence of temperature fluctuations. It is, therefore, important to consider how best to analyze current data so as to minimize the potential importance of such temperature fluctuations.

3.2. Truncated Data Set

A significant contribution to the systematic offset in $Y_p$ in the presence of temperature fluctuations comes from the flattening of the slope of the $Y$-versus-$Z$ relation owing to the large increase in oxygen abundance for the cooler, higher metallicity $\text{H II}$ regions (see Figs. 1 and 2). Therefore,
the uncertainty in $Y_p$ derived from a fit to the trend of $Y$ with O/H might be minimized if the data set is restricted to the H II regions with the very lowest metal abundance that are hotter. To explore this, for each realization of our Monte Carlos we identify the subset of H II regions with low metallicity: O/H $\leq 0.9 \times 10^{-4}$. For these subsets, we fit linear $Y$-versus-$Z$ relations and compare the slopes and intercepts (as well as $\sigma$) to those found for the corresponding low-metallicity subset in the absence of temperature fluctuations. The results are shown in Figures 6 and 7. As expected, the changes in slope and intercept for this low-metallicity set are much smaller. Indeed, the trend is even opposite that for our full data set: lower intercept, higher slope (although the effect is so small as to be only marginally significant). The lesson is clear. If we wish to minimize the uncertainty due to temperature fluctuations in $Y_p$ derived from a fit of $Y$ versus $Z$, we should restrict our attention to the most metal-poor H II regions.

3.3. Lowest-$Y$ H II Regions

Since it is generally accepted that the helium abundance has only increased since the big bang, an alternate approach to using H II regions observations to infer the primordial abundance is to compute the mean of $Y$ for those regions with the lowest helium abundances; then, $Y_p \leq \langle Y \rangle$ (OS; OSS). This estimator is likely to be robust against the sys-

**Fig. 4.**—Distribution of offsets in the primordial mass fraction of $^4$He evaluated for the full data set with $\Delta T_{\text{max}} = 4000$ K for three different temperature-probability distributions (top to bottom: flat, linearly increasing, linearly decreasing).

**Fig. 5.**—Solid curves show the variation of the mean values of the offsets in $Y_p$ (top panel), the ratio of slopes (middle panel), and the dispersion around the best-fit linear $Y$-vs.-$Z$ relation (bottom panel) as a function of $\Delta T_{\text{max}}$. The dotted curves show the 95% CL ranges.
Systematic shifts due to temperature fluctuations. To test this, we have first chosen the 10 H II regions with lowest Y in our fiducial data set ($\Delta T = 0$) and found the unweighted average of $Y$, $\langle Y \rangle_{10}(0)$. Then, from our Monte Carlos, for various choices of $\Delta T_{\text{max}}$, we determine (for each realization) the 10 H II regions with lowest $Y$ (often, but not always, the same as in the fiducial set) and compute $\Delta \langle Y \rangle_{10} = \langle Y \rangle_{10}(\Delta T) - \langle Y \rangle_{10}(0)$. The distributions of $\Delta \langle Y \rangle_{10}$ for $\Delta T_{\text{max}} = 2000$ K and 4000 K are shown in Figure 8, and the trend of $\Delta \langle Y \rangle_{10}$ with $\Delta T_{\text{max}}$ is shown in Figure 9, where the corresponding change in the dispersion around the mean ($\sigma$) is also shown. As expected, although temperature fluctuations tend to increase $\langle Y \rangle_{10}$ systematically (mainly owing to the reduced correction for collisional excitation), the effect is quite small.

4. DISCUSSION

Temperature fluctuations in the low-metallicity, extragalactic H II regions used to infer the primordial helium abundance will lead to systematic offsets in the helium and oxygen abundances derived for those regions. In the absence of direct observations of the hydrogen temperatures for these regions, we have attempted to quantify the effect of such fluctuations on the derived value of $Y_p$ by performing a series of Monte Carlo calculations where the temperature fluctuation for each H II region is chosen from a distribution whose maximum value is varied. $Y_p$ determined from a linear fit to $Y$ versus $O/H$ is especially susceptible to this source of error, which flattens the $Y$-versus-$Z$ relation and results in a higher intercep. This potential systematic error is insidious in the sense that the offset in $Y_p$ may be significant without a noticeable increase in the dispersion of the individual H II-region $Y$ values around the best-fit $Y$-versus-$Z$ relation. To illustrate the possible offsets that may be consistent with extant data, consider the results of OSS for their full data set of 62 H II regions with $O/H \leq 1.5 \times 10^{-4}$: $Y_p = 0.234 \pm 0.005$ (0.005 is a 2 $\sigma$ estimate of the statistical uncertainty). For $\Delta T_{\text{max}} = 4000$ K, we should increase this value by 0.008 $\pm$ 0.004 (see Fig. 5). Adding the (uncorrelated) systematic and statistical uncertainties in quadrature will lead us to $Y_p = 0.242 \pm 0.006$ (95% confidence limit [CL]). Such a large correction to $Y_p$ would ameliorate the “tension” in big bang nucleosynthesis (BBN) (Hata et al. 1995) between primordial helium and the low abundance of deuterium suggested by Galactic observations (see, e.g., Dearborn, Steigman, & Tosi 1995 and references therein) and by some direct detections of deuterium in low-metallicity, high-redshift QSO absorbers (Tytler, Fan, & Burles 1996; Burles & Tytler 1996).

Until data on temperature fluctuations in these key extragalactic H II regions become available, the best strategy is to analyze the current data in a manner that minimizes this potential systematic error. One possibility is to restrict attention to the available regions with the lowest metallicity. OS and OSS have done this for the subset with $O/H \leq 0.9 \times 10^{-4}$ for which OSS derive from a linear fit to $Y$ versus $O/H$: $Y_p = 0.230 \pm 0.007$ (95% CL). From our Monte Carlo simulations of the data, we find for this subset that the systematic correction is likely very small (indeed, it may even be negative!); for $\Delta T_{\text{max}} = 4000$ K, $\Delta Y_p = -0.004 \pm 0.005$ (see Fig. 7). If, perhaps naively, we apply this correction to the OSS result, we infer $Y_p = 0.226 \pm 0.009$ (95% CL). In this case, the tension between primordial helium and low primordial deuterium is exacerbated.

Another "safe" approach to using the existing data to derive an estimate of $Y_p$ is to ignore the metallicity information and simply take a mean $\langle Y \rangle$ of the helium abundance for the lowest abundance H II regions. Since helium is only expected to increase after BBN, this provides an upper bound to $Y_p$. In general, the H II regions with the lowest values of $Y$ tend to be the lowest metallicity regions, which are also the hottest (see Fig. 2). For such regions, there has often been a nonnegligible correction for collisions in deriving $Y$ from the helium-line intensities. If the gas is, in fact, cooler, this correction has been underestimated and the true value of $Y$ should be larger. Thus, temperature fluctuations will increase $\langle Y \rangle$. From our Monte Carlo simulations we have selected, for each realization, the 10 H II regions with the lowest $Y$ values, and we have found, for $\Delta T_{\text{max}} = 4000$ K, a small systematic increase: $\Delta \langle Y \rangle_{10} = 0.002 \pm 0.001$.
Similar to but for the low-metallicity subset of H II regions (O/H < 0.9). For their 10 regions with highest Y, OSS find $<Y>_{10} = 0.230 \pm 0.006$ (95% CL), so that even with our largest correction, we infer a revised mean of $0.232 \pm 0.006$, suggesting that $Y_p \leq 0.238$ (95% CL). Here, too, the tension between D and $^4$He fails to be relieved.

5. SUMMARY

Temperature fluctuations in low-metallicity, extragalactic H II regions may have a significant effect on the determination of the primordial abundance of helium. If present, they may increase the metallicity of the higher metallicity, relatively cooler regions and increase the helium abundance of the more metal-poor, hotter regions, tilting the inferred Y-versus-Z relation and leading to a higher, zero-metallicity intercept ($Y_p$). Such a systematic offset is not necessarily accompanied by a significant increase in the dispersion of the means of the 10 lowest Y H II-region helium abundances as a function of $\Delta T_{\text{max}}$. (see Figs. 8 and 9).

FIG. 8.—Distribution of offsets in the means of the 10 lowest Y H II-region helium abundances for $\Delta T_{\text{max}} = 2000$ K (shaded histogram) and $\Delta T_{\text{max}} = 4000$ K.

persion of the data around the best-fit linear $Y$-versus-$Z$ relation and, therefore, may remain invisible in the absence of direct data on temperature differences in these regions. It is clear that such data is crucial to constraining the uncertainty in $Y_p$. In the absence of such data, we have noted that restricting attention to the regions of lowest metallicity ($Z \leq Z_{C/10}$) will tend to minimize this systematic offset. Alternatively, the mean of the helium abundances of the $H_\Pi$ regions with the lowest $Y$ is also robust against the effect of temperature fluctuations.

S. M. V. and R. G. owe a debt of gratitude to P. Benevides-Soares for valuable discussions. The work of S. M. V. and R. G. is partially supported by FAPESP and CNPq in Brazil; that of G. S. is supported by the DOE. This work was initiated when S. M. V. and G. S. were visiting the INT at the University of Washington, and they are grateful for the hospitality and stimulating environment provided there.
