The traumatized ischiopubic synchondrosis: a rare cause of acute hip pain

Justus H. W. Jansen · Aernout R. J. Langeveld · J. A. Niesten

Introduction

Epiphyseal growth plates developing during skeletal maturation are the most common temporary synchondroses in childhood. The fibrocartilaginous bridge between the superomedial pubic and the inferolateral ischial ossification center is defined as the ischiopubic synchondrosis (IPS). It is considered to be a physiologic developmental stage that can be recognized on conventional radiographs as a fusiform radiolucent area at the ischiopubic zone [1, 2]. The ossification of IPS begins early in childhood and is usually completed before puberty. While usually asymptomatic, the ossification process can be accompanied by pain in the groin and restriction in the movement of the hip joint [3, 4].

Although stress fractures have been described to mimic the symptomatic IPS ossification, a traumatic fracture of the IPS as a cause of hip pain has not yet specifically been reported.

Case report

An otherwise healthy 8-year-old girl visited our orthopedic outpatient department in a wheelchair. Almost 2 weeks earlier, she had fallen on her left hip during ice-skating. Although she was able to continue her activity, increasing pain on the lateral side of her left hip had caused her to limp progressively over the next couple of days. At the time of presentation, she could not bear weight. There was no history of recent illness.

Physical examination of the hips did not reveal signs of hematoma, infection, or other external abnormalities. There was clear tenderness on palpation around the greater trochanteric area on the lateral side of the left hip. Hip movement was slightly diminished and painful on the lateral side of the hip, but not in the groin.

The pelvic AP and Lauenstein radiographs did not show indications of a fracture, epiphysiolysis, or Perthes disease. Bilateral radiolucent fusiform widening of the IPS was considered physiological (Fig. 1). Blood laboratory tests showed no abnormalities, with normal leukocyte count, C-reactive protein levels, and sedimentation rate.

Adaptation of weight bearing was advised. As the pain continued to prevent her from bearing weight over the next couple of weeks, additional pelvic MR imaging was performed. A hypointense linear band was observed in both left and right IPS on T1 and T2. On the left side, a hyperintense signal of the ischiopubic zone and adjacent soft tissue was seen on T2 with fat saturation (Fig. 2). Combined with the clinical presentation, a fracture of the left IPS was diagnosed.

A watchful waiting policy was deployed that resulted in a spontaneous improvement of pain and hip function. Three months after the traumatic event, all symptoms had subsided.

Discussion

Acute unilateral hip pain during childhood can be a diagnostic challenge [5, 6]. Septic arthritis and epiphysiolo-
ysis require prompt treatment and should be ruled out. In addition, non-specific clinical presentation in children may warrant a clear diagnosis. While traumatic lesions of the IPS are uncommon and usually not visible using plain radiographs, they can easily be missed.

Additional pelvic MR imaging is helpful to diagnose such a lesion, although interpretation can be challenging. Signal alterations of the ischiopubic fusion zone in the asymptomatic IPS are frequently observed. Herneth et al. retrospectively screened for IPS on pelvic MR imaging performed in children [7]. They found IPS with signal alteration of the ischiopubic fusion zone to occur in 61% of their population. Typically, a hyperintense signal on T2 with fat saturation or STIR, and a hypointense signal on T1 is noted. Additionally, fibrous bridging and fusiform swelling can be observed, accompanied by signal alteration of the adjacent soft tissue. Although usually presenting bilaterally, IPS signal alterations on MR imaging were found to occur unilaterally in one third of the population.
