(Received 21 June 1996)

We study the properties of the superdeformed (SD) bands of $^{195}\text{Pb}$ and $^{193}\text{Hg}$ by the cranked Hartree-Fock-Bogoliubov method. Our calculations reproduce the flat behavior of the dynamical moment of inertia of two of the SD bands of $^{195}\text{Pb}$ measured recently. We discuss possible configuration assignments for the observed bands 3 and 4 of $^{195}\text{Pb}$. We also calculate the two interacting SD bands of $^{193}\text{Hg}$. Our analysis confirms the merit of density-dependent pairing forces as compared to seniority pairing interactions.

I. INTRODUCTION

The dynamical moment of inertia $J$ of most superdeformed (SD) bands observed in nuclei of the $A \approx 190$ region are increasing functions of the angular velocity $\omega$ [1–14]. Recently, Farris et al. [12] found that $J$ is almost constant versus $\omega$ for the two lowest SD bands in $^{195}\text{Pb}$. This new feature is particularly interesting. In the same nucleus two other bands have been observed which display the usual increasing trend. It appears natural to attempt an explanation of these various behaviors of the SD bands of $^{195}\text{Pb}$ in terms of their quasiparticle (qp) structure. According to most theoretical investigations in the $A = 190$ region, the neutron qp’s relevant for neutron numbers above the $N = 112$ gap are built on the $[752]5/2$, $[512]5/2$, and $[624]9/2$ orbitals [15–18]. In this work, we analyze the properties of the SD bands of the two odd-$N$ neighboring nuclei $^{195}\text{Pb}$ and $^{193}\text{Hg}$ [5] which today provide the richest information set on the neutron structure in the $A = 190$ superdeformed well. Our work is based on the cranked Hartree-Fock-Bogoliubov (HFB) approach which has been shown to reproduce with a good accuracy the SD band properties of even nuclei [19,20]. As in Ref. [18], the mean-field method has been corrected by means of the Lipkin-Nogami prescription [21–23] to take into account the finite number of nucleons. The nucleon-nucleon effective interaction in the particle-hole channel is the Skyrme force within the Skm$^*$ parametrization [24]. In the pairing channel we use a zero-range force with a surface-peaked density dependence as described in Ref. [20]. In a previous study of the yrast SD band of $^{194}\text{Pb}$, this type of force was shown to improve significantly the alignment properties which determine the saturation of $J$ for large values of $\omega$.

Our method of solution of the HFB equation combines the imaginary-time evolution method to determine the basis which diagonalizes the mean-field Hamiltonian and a diagonalization of the HFB Hamiltonian matrix to construct the canonical basis. Details can be found in Ref. [18]. The different bands of the odd nuclei we are concerned with, are described by the self-consistent creation of the appropriate qp [25] on the even vacuum. This requires some care in the numerical treatment, since, except at zero angular velocity, parity, and signature are the only quantum numbers available for sorting qp’s. Therefore, we rely mostly on continuity properties versus $\omega$ to follow a given SD band.

The first part of this paper is devoted to a study of $J$ and qp Routhian (qpR) properties of $^{195}\text{Pb}$. In the second part we analyze how the structure of the pairing force affects SD properties by comparing the results for $^{193}\text{Hg}$ with the density-dependent interaction with those of Ref. [25] in which a seniority interaction was used.

II. SUPERDEFORMATION IN $^{195}\text{Pb}$

A. Dynamical moment of inertia

In Fig. 1 we compare the dynamical moments of inertia $J$ of the four observed bands [12] with those calculated for the seven SD bands built on the $[752]5/2$, $\alpha = \pm 1/2$, $[512]5/2$, $\alpha = \pm 1/2$, $[624]9/2$, $\alpha = \pm 1/2$, and $[642]3/2$, $\alpha = -1/2$ orbitals. The SD bands built on the intruder $\nu$ [752]5/2 bands display a small variation of $J$ for $\hbar \omega \approx 0.24$ MeV. It seems therefore reasonable to assign them to the first and second experimental bands. The observed significant signature splitting is also reproduced and suggests that the band with lowest moment of inertia has a positive signature. For bands 3 and 4 the authors of Ref. [12] have argued that they may be built on $\nu[624]9/2$ orbitals. On the other hand, the theoretical part of their analysis indicated that transition energies associated with $\nu[624]9/2$ and $\nu[512]5/2$ bands would be almost identical. This is supported by our results.

*Unité de recherches des Universités Paris XI et Paris VI associée au CNRS.
Indeed we find that the moment of inertia of the $\nu[624]9/2$ bands is very similar to that of the $\nu[512]5/2$ bands for $\hbar\omega \approx 0.24$ MeV. Both sets of $\mathcal{J}$ agree qualitatively with those observed for bands 3 and 4. Based on the sole information given by the moment of inertia, it is therefore not possible to decide whether bands 3 and 4 should be labeled $\nu[624]9/2$ or $\nu[512]5/2$. We only note a small signature splitting for the $\nu[512]5/2$ when $\hbar\omega \geq 0.3$ MeV. A complementary piece of information is provided by the excitation energy $E_{\text{rel}}$ of the bands with respect to each other. It is generally believed that this quantity which is directly available in the calculation (see Table I) is correlated with the observed relative population of the bands. In Table I, the reference energy corresponds to the state of $\nu[752]5/2$, $\alpha = -1/2$ band of the angular momentum $I = 32.5$; it has been calculated by averaging two energies of $I = 31.5$ and 33.5. The relative excitation energies $E_{\text{rel}}$ of the other negative-signature bands were calculated in the same way. According to Table I, the $\nu[752]5/2$ bands are the lowest, the $\nu[512]5/2$ bands are second lowest and the $\nu[624]9/2 \nu[642]3/2$ bands are the most excited. Therefore, for the $\nu[752]5/2$ bands, the agreement of our calculation with experiment concerns both the magnitude and behavior of moments of inertia and the excitation energy. On the other hand, we are led to assign a $\nu[512]5/2$ structure to bands 3 and 4. We note, however, that the energy differences in Table I are of the order of 0.1 MeV. Such a precision is below the limit of physical credibility of a calculation such as ours when it comes to the relative position of orbitals. We shall return to this point when discussing the crossing phenomenon in $^{193}\text{Hg}$.

**B. Deformation**

The charge quadrupole moments $Q_c$ of the $\nu[512]5/2$ and $\nu[624]9/2$ bands are shown in Fig. 2. They differ by approximately 0.3 b which is probably too small to be measured. As expected for bands with large $m$ values no signature splitting is found. The quadrupole moments of the intruder bands are slightly more different: 19.96 eb at $I = 32.5$ ($\hbar\omega = 0.314$ MeV) for $\alpha = +1/2$ and 19.47 eb at $I = 31.5$ ($\hbar\omega = 0.290$ MeV) for its signature partner. Differences between the magnetic moments of the $\nu[512]5/2$ and $\nu[624]9/2$ bands can lead to different crosstalks between the bands. However, their values are rather similar ($\approx 12.4\mu_N$, $\mu_N$ being the nuclear magneton, at $I = 31$) for the four bands. Both the quadrupole and the magnetic moments do not provide a relevant signature to establish the nature of the third and fourth SD bands.

**C. Quasiparticle energies**

Let us now consider the evolution of the qpR’s versus $\omega$. As the mean-fields are self-consistently modified by the

---

We have taken the cranking axis as approximate quantization axis in evaluating the magnetic moment at $\hbar\omega = 0.3$ MeV. Semmes et al. [26] have calculated the magnetic moments in the framework of the particle-rotor model with the strong-coupling scheme. They obtained a value of $-0.48$ for the $g$ factor of the $\nu[512]5/2$ band of $^{193}\text{Hg}$.

**TABLE I. Calculated relative excitation energies $E_{\text{rel}}$ of the six SD bands in $^{195}\text{Pb}$ at $I = 32.5$. The reference band is $\nu[752]5/2$, $\alpha = -1/2$ band. $E_{\text{rel}}$ of the negative-signature bands were calculated from averages of energies of $I = 31.5$ and 33.5.**

| Band          | $E_{\text{rel}}$ [MeV] |
|---------------|------------------------|
| $\nu[752]5/2$, $\alpha = +1/2$ | 0.125 |
| $\nu[752]5/2$, $\alpha = -1/2$ | 0.000 |
| $\nu[512]5/2$, $\alpha = +1/2$ | 0.168 |
| $\nu[512]5/2$, $\alpha = -1/2$ | 0.172 |
| $\nu[624]9/2$, $\alpha = +1/2$ | 0.297 |
| $\nu[624]9/2$, $\alpha = -1/2$ | 0.297 |
| $\nu[642]3/2$, $\alpha = -1/2$ | 0.368 |

![FIG. 1. (a) Experimental dynamical moments of inertia of the four SD bands [12] of $^{195}\text{Pb}$. (b) HFB dynamical moments of inertia of the lowest SD bands of $^{195}\text{Pb}$. (The negative signature bands are denoted with black symbols.)](image-url-1)

![FIG. 2. Calculated charge quadrupole moments $Q_c$ of the $\nu[512]5/2$, $\nu[624]9/2$ bands and the $\nu[642]3/2$, $\alpha = -1/2$ band of $^{195}\text{Pb}$. Correspondence between the symbols and the SD bands is the same as in Fig. 1(b).](image-url-2)
creation of a qp, the behavior of the qpR’s are not the same for the six SD bands and differ also from those calculated for \( ^{194}\text{Pb} \). In Figs. 3 and 4 we show the neutron qpR’s for the \( \nu[752]5/2, \alpha = -1/2 \) (after a crossing with \([512]5/2, \alpha = -1/2\)) and \( \nu[624]9/2, \alpha = +1/2 \) bands respectively. In each figure, the thick curve indicates which qp is occupied.

In self-consistent calculations, such as those discussed in the present work, the interpretation of qp diagrams requires some care. First of all let us recall that qp energies and Routhians are not observables: they are not eigenvalues of a Hamiltonian which depends both on the nucleus and on the configuration which characterizes them for large values of angular momentum.

On Figs. 3 and 4 we have drawn the qp energies (eigenvalues of the HFB Hamiltonian which depends both on the nucleus and on the configuration) corresponding to the self consistent vacuum associated with two different 1-qp excitations. These diagrams differ from those of the two neighboring even isotopes. Two factors play a role. First, the Fermi level is displaced to ensure that the average number of particles is equal to 113. Second, the excitation of a 1-qp creates specific time odd contributions to the mean field which do exist even in the absence of rotation. These terms are responsible for a splitting between signature partner Routhians at \( \hbar \omega = 0 \). Of course, the creation of a 1-qp excitation in the signature partner orbital (and a change \( \omega \leftrightarrow -\omega \)) would simply lead to a similar qp diagram with an exchange of signature for all the curves. A question still not understood is the sign and the magnitude of these splittings. In particular, we notice that they are especially large for the pair out of which the qp is created.

On the other hand, in a study of excited states in an even nucleus, one can consider a 2-qp state built on a signature partner pair. In such case, time reversal invariance is restored at \( \hbar \omega = 0 \) and no splitting occurs in the absence of cranking. However, due to self-consistency effects, the qp spectrum will differ from that of the 0-qp configuration. One of the main consequences of the modification of the Routhian spectrum is the displacement of level-crossings frequencies compared to the values expected from the consideration of the qp spectrum of the neighboring even nuclei. In particular, we notice that the average curvature of the \( \nu[752]5/2, \alpha = +1/2 \) Routhian is the smallest consistent with the low moment of inertia of the corresponding band.

The accident in the theoretical \( J \) for the \([752]5/2 \) and \([512]5/2 \) bands for \( 0.1 < \hbar \omega < 0.2 \text{ MeV} \) is generated by a band crossing. Such a feature can always happen when two crossing bands have the same quantum numbers. In case of a band crossing, our convention is to denote bands with the qp configuration which characterizes them for large values of \( \hbar \omega \). For values of \( \hbar \omega \) near 0.15 MeV, both for the \([752]5/2 \) and \([512]5/2 \) bands, we have not been able to obtain solutions satisfying the angular-momentum constraint accurately. We have met numerical instabilities caused by the near degeneracy both in energy and angular momentum. A correct physical solution of this problem requires a self-consistent configuration mixing calculation which is beyond the scope of this study. As a band crossing has not been observed in \( ^{190}\text{Pb} \), we infer that the calculation shown in Fig. 3 overestimates the energy difference between the \([752]5/2, \alpha = -1/2 \) and \([512]5/2, \alpha = -1/2 \) energies at \( \omega = 0 \) by at least 0.1 MeV. A possible way to remedy this deficiency, is to correct the mean field in such a way that the energy of the \([512]5/2, \alpha = -1/2 \) is pushed up, leading to a crossing below the lowest observed \( \hbar \omega \). According to the above discussion, the associated excitation energy of the \([512]5/2 \) SD bands will increase and possibly modify our assignment for band 3 and 4, leading to a better agreement with the conclusions of Ref. [12].

Let us mention the relative position of \( \nu[624]9/2, \alpha = +1/2 \) in Fig. 4. The qpR is not the lowest in Routhians having the positive parity and positive signature. It is anticipated, however, that a particle-type qpR (\( \nu[624]9/2 \)) becomes lower than a hole-type one (\( \nu[642]3/2 \)) in \( ^{195}\text{Pb} \) when
their energies are comparable for the yrast SD band of $^{194}$Pb. Given the present uncertainty of mean-field calculation concerning the detailed relative location of the qpR’s, we cannot disregard $\nu(624)/2$ as a candidate for the configuration of bands 3 and 4.

On Fig. 2 and in Table I we have also reported result for the negative signature band built on the $\nu(624)/2, \alpha = -1/2$ quasiparticle. Although the Routhian of this state is lower than that of the $\nu(624)/2$ in the quasiparticle spectrum of $^{194}$Pb. Table I shows that the [624]/2 SD band is more excited. This is a direct consequence of self-consistent effects.

III. SUPERDEFORMATION IN $^{193}$Hg

Let us now see how these considerations can be extended to the analysis of the nucleus $^{193}$Hg. So far six SD bands including two identical bands have been observed [5]. Within the HFB method we have already performed a study using the same Skyrme force parametrization for the mean field [25]. However, in this earlier work, pairing correlations were described with a seniority interaction. Figure 5 shows together with the experimental data the results of the present analysis limited to the two interacting bands $\nu(752)/2, \alpha = -1/2$ band (band 4) and $\nu(512)/2, \alpha = -1/2$ band (band 1) with a zero-range density dependent pairing force. For each band a separate HFB calculation has been performed. Our calculation shows that this dual self-consistent HFB analysis is able to reproduce the observed band interaction. This is a significant improvement over the calculation of Ref. [25] in which no interaction was found. It provides an additional indication of the superiority of a surface-type zero-range pairing force over a seniority interaction. On the other hand, the angular velocity at which bands interact is found at $\hbar\omega \approx 0.15$ MeV instead of the observed value $\hbar\omega \approx 0.25$ MeV. This difference may reflect an incorrect of the relative location of the relevant qpR’s in $^{193}$Hg which would then be consistent with our discussion on the position of orbitals [752]/2 and [512]/2 in $^{195}$Pb.

IV. CONCLUSION

In summary, we have analyzed the properties of the SD bands of two odd-$N$ nuclei $^{195}$Pb and $^{193}$Hg by making use of the cranked HFB method. Our self-consistent calculation has confirmed the general belief that the flat behavior of $\mathcal{J}$ in bands 1 and 2 of $^{195}$Pb is related to the curvature of the neutron intruder qpR. For bands 3 and 4 we have found that configurations based on the [624]/2 and [512]/2 are in competition. Both the moment of inertia, the quadrupole moments and the magnetic moments of these four SD bands are very similar. In particular, within the HFB method these quantities do not provide a relevant mean to decide the nature of the observed bands 3 and 4. We have also calculated the two interacting SD bands of $^{193}$Hg with qualitative success. The results of this analysis provide additional support for an effective pairing force acting predominantly at the nuclear surface. The quantitative inaccuracy on the position of the crossing frequencies ($\Delta \hbar\omega \approx 0.1$ MeV) could be an indication that qpR associated with the [512]/2 is too low by 0.1 MeV relative to the rest of the spectrum. It is an interesting and open question whether it is possible to determine an effective interaction with the same global qualities of the SkM* force which could also achieve a better precision as regards the single-particle energies.

ACKNOWLEDGMENTS

We thank J. Becker and L. Farris for discussions on the experimental results. This work has been partly supported by the ARC Convention No. 93/98-166 of the Belgian SSTC.
