It is well known that the interaction of quantum systems with the environment reduces the inherent quantum correlations. Under special circumstances the effect of decoherence can be reversed, for example, the interaction modeled by an amplitude damping channel can boost the teleportation fidelity from the classical to the quantum region for a bipartite quantum state. Here, we first show that this phenomena fails in the case of a quantum key distribution protocol. We further show that the technique of weak measurement can be used to slow down the process of decoherence, thereby helping to preserve the quantum key rate when one or both systems are interacting with the environment via an amplitude damping channel. Most interestingly, in certain cases weak measurement with post-selection where one considers both success and failure of the technique is shown to be more useful than without it when both systems interact with the environment.

I. INTRODUCTION

Correlations between quantum systems can not always be explained by local causal theory [1, 2]. This nature of quantum correlations helps to perform certain information processing tasks, for example, quantum teleportation [3], super dense coding [4] and quantum key distribution [5, 6], which are not possible using classical correlations. However, in practice, quantum systems are continuously interacting with the environment, and this interaction weakens the correlations between observed quantum systems. Hence, the most crucial task in quantum information processing is to protect quantum correlations from diminishing due to the effect of the ubiquitous environment.

Under special circumstances, interaction between systems and a common environment can generate entanglement [7]. For example, when two or more atoms are consecutively passing through a cavity, they become entangled [8, 9]. Although, for a specific information processing task, viz. quantum teleportation, the environmental interaction modeled by an amplitude damping channel (ADC) can enhance the fidelity of quantum teleportation of those bipartite states whose teleportation fidelity lies just below the quantum region [10], this improvement of fidelity is found to be possible only for a certain class of bipartite states [11–15].

Moreover, one can use the technique of weak measurements to protect the fidelity of quantum teleportation when systems are interacting with the environment modeled by an amplitude damping channel [13–19]. The idea of weak measurements was originally proposed [20] on the basis of weak coupling between the observed system and the measurement device, thereby making possible for the measurement outcomes to be amplified compared to the eigenvalue spectrum of original system, for suitable post-selected ensembles. This technique has been implemented in many different ways, such as in the study of the spin Hall effect [21], superluminal propagation of light [22], wave particle duality using cavity-QED experiments [23], direct measurement of the quantum wave function [24], measurement of ultrasmall time delays of light [25], and observing Bohmian trajectories of photons [26, 27].

In the present work, we study the possibility of preservation of the quantum key rate for a bipartite state shared between Alice and Bob where Alice’s system is not trusted as a quantum system. More specifically, we discuss a way to protect the one-sided device independent quantum key distribution (1s-DIQKD) protocol [28] when the system interacts with the environment modeled by ADC. Comparing the preservation of 1s-DIQKD with the preservation of the fidelity of quantum teleportation, we observe that ADC cannot improve the optimal secret key rate in 1s-DIQKD, which is derived using the steering inequality [29] based on the fine-grained uncertainty relation [30], though it can improve the teleportation fidelity for states having teleportation fidelity just below the quantum region [11–12]. We show that improvement of the key rate becomes possible using the technique of weak measurement and its reversal, which may be used to suppress the effect of the amplitude damping decoherence [13–19].

This paper is organized as follows. In Sec. II, we briefly recapitulate the technique of weak measurement and its reversal in the presence of an interaction of the system with the environment as modeled by ADC. In Sec. III we discuss the connection of steerability with quantum key distribution for the case of the 1s-DIQKD protocol [29]. In Sec. IV we demonstrate the effect of the amplitude damping decoherence on the steerability and key rate.

In Sec. V we show how the technique of weak measurement and its reversal can be used to protect the key rate. Finally, in Sec. VI we summarize the main results of this work.

II. WEAK AND REVERSE WEAK MEASUREMENT IN THE PRESENCE OF AN AMPLITUDE DAMPING CHANNEL

Let us consider that a qubit is prepared either in the state $|0\rangle_S$ or in the state $|1\rangle_S$. The qubit is allowed to interact with the environment by ADC, where the environment is initially in the state $|0\rangle_E$. Due to the effect of decoherence, the combined state of the system and environment becomes

$$|0\rangle_S|0\rangle_E \rightarrow |0\rangle_S|0\rangle_E,$$

$$|1\rangle_S|0\rangle_E \rightarrow \sqrt{D_S}|1\rangle_S|0\rangle_E + \sqrt{D_S}|0\rangle_S|1\rangle_E,$$

where $D_S$ is the strength of the system with environment and $\sqrt{D_S} = 1 - D_S$. In practice, the photon loss when the photon is passing through the environment can be regarded as amplitude damping decoherence. The above interaction (1) can be written as a positive and trace preserving map $\Lambda$ given by

$$\Lambda(\rho) = W_{S,0} \rho W_{S,0}^\dagger + W_{S,1} \rho W_{S,1}^\dagger,$$

where

$$W_{S,0} = \begin{pmatrix} 1 & 0 \\ 0 & \sqrt{D_S} \end{pmatrix}; \quad W_{S,1} = \begin{pmatrix} 0 & \sqrt{D_S} \\ 0 & 0 \end{pmatrix},$$

and $\sum_{i=0}^{1} W_{S,i} = I$.

It has been shown in earlier works [14]-[18] that the technique of weak measurement and its reverse can suppress the environmental effect modeled by ADC. Here, before allowing interaction with the environment, the system is measured using a scheme of weak quantum measurement, with strength $p_S$. More specifically, the detector detects the system with probability $p_S$ if and only if the system is in the state $|1\rangle_S$. When the detector detects, the corresponding Kraus operator is given by

$$M_{S,1} = \begin{pmatrix} 0 & 0 \\ 0 & \sqrt{p_S} \end{pmatrix},$$

which does not have any inverse. Hence, this operation, i.e., the detection is irreversible. The operator when the system is not detected is given by

$$M_{S,0} = \begin{pmatrix} 1 & 0 \\ 0 & \sqrt{1-p_S} \end{pmatrix}.$$

The operator $M_{S,0}$ is reversible, i.e., the application of its inverse restores the system to its initial state. The case where the system is detected will be discarded. Hence, weak measurement is associated with a success probability.

After performing weak measurement, the system is allowed to interact with the environment and at the end, to reduce the affect of environment, reverse weak measurement is performed. The operator corresponding the case when the system is not detected is given by

$$N_{S,0} = \begin{pmatrix} \sqrt{q_S} & 0 \\ 0 & 1 \end{pmatrix},$$

where $q_S$ is the strength of the reverse weak measurement.

III. STEERING AND ITS CONNECTION WITH 1S-DIQKD

Non-local quantum correlations between two systems, say A and B, can be categorized separately by entanglement, steering and Bell non-local correlation [31], respectively. In the case of entanglement, both A and B are trusted as quantum systems, whereas, none of them is trusted as a quantum system in Bell non-local correlation. In the intermediate case of steering, one of them is trusted as a quantum system and the shared state, $\rho_{AB}$ is said to be entangled if it cannot be described by a local hidden state model (LHS) [31]. There are different steering criteria based on different uncertainty relations [29, 32–34]. In the present work we use the optimal fine-grained steering criteria to study the quantum key rate of steerable states [29].

To discuss fine-grained steering, let us consider the following game. Alice prepares a large number of bipartite quantum states $\rho_{AB}$. She then sends all the systems B to Bob and keeps the systems A with her. Bob only trusts that the system B is quantum, but agrees that the prepared state is entangled if and only if Alice has control on the state of systems B. In other words, $\rho_{AB}$ is said to be steerable when it cannot be explained by a local hidden state model [31]. To check whether the state is steerable, Bob asks Alice to control the state of his system B in one of the eigenstates of the observable chosen randomly from the set $\{\sigma_z, \sigma_x\}$. Next, Alice measures a suitable observable chosen from the set $\{A_1, A_2\}$ and communicates her choice and outcome. The shared state $\rho_{AB}$ is steerable when the conditional probability distribution $P(b_{\sigma_z}|a_{A_1})$ (where $b$ and $a$ are measurement outcomes at Bob’s and Alice’s side) violates the relation [29]

$$\frac{1}{2} \mid P(b_{\sigma_z}|a_{A_1}) + P(b_{\sigma_x}|a_{A_1}) \mid \leq \frac{3}{4}. \quad (7)$$

In Ref. [29], it has been further shown that if the shared state $\rho_{AB}$ between systems A and B is maximally steerable, then none of these systems can be quantumly correlated, or steerable with any other system – this phenomenon is called monogamy of steerable states. This nature of steerable states lower bounds the secret key rate in
a one-sided device independent way, i.e., one of the systems is not trusted. The lower bound of the secret key rate $r$, corresponding to $\rho_{AB}$ which violates the above inequality (7) is given by 29

$$r \geq \log_2 \left[ \frac{\delta + 3}{3 - \delta} \right] ,$$  (8)

where $\delta$ is the degree of violation of the inequality.

IV. LOWER BOUND OF QUANTUM KEY RATE UNDER AMPLITUDE DAMPING CHANNEL

In the above section, we have discussed the connection of the secret key rate with steerability. In the considered steering game, Alice needs to send the quantum system of the secret key rate with steerability. In the considered environment interaction, the shared state between Alice’s system and Bob’s system interacts with environment is thus given by through the environment. In the second case, “Case-II”, we discuss the effect on the key rate when both systems interact with the environment through amplitude damping decoherence. In both the cases we assume that Alice prepares the systems $A$ and $B$ in one of the maximally entangled states given by

$$|\psi^\pm\rangle = |00\rangle \pm |11\rangle, $$

$$|\phi^\pm\rangle = |01\rangle \pm |10\rangle. $$  (9)

Case I. Here we discuss the environmental effect on the steerability when the system interacts with environment via ADC during the time of its passage. After environmental interaction, the shared state between Alice’s system $A$ and Bob’s system $B$ becomes

$$\rho_{AB}' = (I \otimes W_{2,0}) |\psi^\pm\rangle \langle \phi^\pm| (I \otimes W_{2,0})'$$

$$+ (I \otimes W_{2,1}) |\psi^\pm\rangle \langle \phi^\pm| (I \otimes W_{2,1})',$$

$$= \left( \begin{array}{cccc}
\frac{1}{2} & 0 & 0 & \pm \sqrt{\frac{1-D_2}{2}} \\
0 & \frac{1-D_2}{2} & 0 & 0 \\
0 & 0 & \frac{D_2}{2} & 0 \\
\pm \sqrt{\frac{1-D_2}{2}} & 0 & 0 & \frac{1-D_2}{2}
\end{array} \right) ,$$  (10)

when Alice prepares the initial state $|\psi^\pm\rangle$ given by Eq. (9), or

$$\sigma_{AB}' = (I \otimes W_{2,0}) |\phi^\pm\rangle \langle \phi^\pm| (I \otimes W_{2,0})'$$

$$+ (I \otimes W_{2,1}) |\phi^\pm\rangle \langle \phi^\pm| (I \otimes W_{2,1})',$$

$$= \left( \begin{array}{cccc}
\frac{D_2}{2} & 0 & 0 & \pm \sqrt{\frac{1-D_2}{2}} \\
0 & \frac{1-D_2}{2} & 0 & 0 \\
0 & \pm \sqrt{\frac{1-D_2}{2}} & \frac{D_2}{2} & 0 \\
0 & 0 & 0 & 0
\end{array} \right) ,$$  (11)

where Alice prepares the initial state $|\phi\rangle$ given by Eq. (9). The Kraus operators $W_{2,0}$ and $W_{2,1}$ are given by Eq. (3). The strength of the environmental interaction with the system $B$, $D_2$ lies in the range $0 \leq D_2 \leq 1$.

Next, we discuss the steerability and the lower bound of the key rate of the state $\rho_{AB}' (\sigma_{AB}')$. We calculate the maximum value of the quantity $\sqrt{[P(b_{\sigma_z}|a_{z_1}) + P(b_{\sigma_z}|a_{z_2})]/2}$ (left-hand side of Eq. (7)), where maximization is taken over Alice’s choice of observables $A_1$ corresponding to spin measurement along the direction $n_1$, and $A_2$ along the direction $n_2$. For both the prepared states $|\psi^\pm\rangle$ and $|\phi\rangle$, the above quantity becomes

$$\frac{1}{2} (P(b_{\sigma_z}|a_{\sigma_z}) + P(b_{\sigma_z}|a_{\sigma_z})) = \frac{3 + \sqrt{1-D_2}}{4} ,$$  (12)

where Alice’s optimal measurement setting is spin measurement along the $z$-direction ($x$-direction) when Bob measures along that direction, i.e., $A_1 = \sigma_z (A_2 = \sigma_x)$. The lower bound of the key rate when the system $B$ interacts with environment is thus given by

$$r_B = \log_2 \left[ \frac{3 + \sqrt{1-D_2}}{3 - \sqrt{1-D_2}} \right] .$$  (13)

Case II. Now we consider that both systems, $A$ and $B$ interact with environment under amplitude damping decoherence. After environmental interaction of both systems, the shared state becomes either

$$\rho_{AB}'' = (W_{1,0} \otimes I) \rho_{AB}' (W_{1,0}^\dagger \otimes I)$$

$$+ (W_{1,1} \otimes I) \rho_{AB}' (W_{1,1}^\dagger \otimes I),$$

$$= \left( \begin{array}{cccc}
\frac{1+D_1D_2}{2} & 0 & 0 & \pm \sqrt{\frac{D_1D_2}{2}} \\
0 & \frac{D_1D_2}{2} & 0 & 0 \\
0 & 0 & \frac{D_1D_2}{2} & 0 \\
\pm \sqrt{\frac{D_1D_2}{2}} & 0 & 0 & \frac{D_1D_2}{2}
\end{array} \right) ,$$  (14)

where $\rho_{AB}'$ is given by Eq. (10), or

$$\sigma_{AB}'' = (W_{1,0} \otimes I) \sigma_{AB}' (W_{1,0}^\dagger \otimes I)$$

$$+ (W_{1,1} \otimes I) \sigma_{AB}' (W_{1,1}^\dagger \otimes I),$$

$$= \left( \begin{array}{cccc}
\frac{D_1+D_2}{2} & 0 & 0 & \pm \sqrt{\frac{D_1D_2}{2}} \\
0 & \frac{D_1D_2}{2} & 0 & 0 \\
0 & \pm \sqrt{\frac{D_1D_2}{2}} & \frac{D_2}{2} & 0 \\
0 & 0 & 0 & 0
\end{array} \right) ,$$  (15)
where \(\sigma'_{AB}\) is given by Eq. (11). Again, for both the states \(\rho'_{AB}\) and \(\sigma'_{AB}\), the optimal set of measurement settings for Alice is \(\{A_1 = \sigma_z, A_2 = \sqrt{1-D^2}\sigma_z - D\sigma_x\}\), where we consider both systems \(A\) and \(B\) interact with the same environment, i.e., \(D_1 = D_2 = D\). The left-hand side of Eq. (7) becomes

\[
\frac{1}{2} [P(b_{\sigma_+}|a_{A_1}) + P(b_{\sigma_-}|a_{A_2})] = \frac{3 + D + 2D^2 + \sqrt{1-D^2}}{4 + 4D}
\]

when the shared state is \(\rho'_{AB}\), and

\[
\frac{1}{2} [P(b_{\sigma_+}|a_{A_1}) + P(b_{\sigma_-}|a_{A_2})] = \frac{3 + 3D + \sqrt{1-D^2}}{4 + 4D}
\]

when the shared state is \(\sigma'_{AB}\). In Fig. 1 and Fig. 2, we plot the respective key rates with the strength of environmental interaction, \(D\). From these two figures it is clear that key rate when both systems interact with environment is lower in comparison with the key rate when a single system interacts with environment, for all value of the interaction strength \(D\). It is worth recounting here that for the amplitude damping channel, the teleportation fidelity can be improved between two parties when both of them are made to interact with the environment [11–13]. Such a phenomenon occurs because the decoherence effect on both systems can improve the classical correlation between them, enhancing in turn the teleportation fidelity. However, no such effect occurs for the quantum key rate which is associated with the quantum correlation of steerability.

V. IMPROVEMENT OF QUANTUM KEY RATE USING THE TECHNIQUE OF WEAK MEASUREMENT AND ITS REVERSAL

It is already known that the technique of weak measurement and its reversal can reduce the environmental effect modeled by ADC, i.e., it helps to protect quantum correlations [13–18]. In the case of preservation of teleportation fidelity [13], both classical correlation and quantum correlations are involved. In the present work, we discuss the preservation of quantum correlations in the form of steerability with the help of the technique of weak measurement and its reversal. Similar to the above section, here, we consider two cases, Case I where environment affects the system \(B\) at time of traversal and Case II where environment affects both systems.

Case I. To protect against the decoherence effect, Alice makes a weak measurement with strength \(p_2\) on the system \(B\) and considers the case when the system \(B\) is not detected. In this case, depending upon the chosen initial state \(\rho^+_W\) or \(\sigma^+_W\) the combined state of the systems \(A\) and \(B\) either becomes

\[
\rho_W = (I \otimes M_{2,0}) \rho_{AB}^+ (I \otimes M_{2,0}^+)\]

or becomes

\[
\sigma_W = (I \otimes M_{2,0}) \sigma_{AB}^+ (I \otimes M_{2,0}^+)\]

where \(M_{2,0}\) is defined in Eq. (5) and \(\rho_W\) (\(\sigma_W\)) is unnormalized. When the system \(B\) is detected, Alice discards the state. Hence, the success probability of generating the state \(\rho_W\) (\(\sigma_W\)) is given by \(Tr[\rho_W] = Tr[\sigma_W] = 1 - D_2/2\). Next, Alice sends the system \(B\) to Bob through the environment. Due to environmental interaction via ADC, the shared state becomes either

\[
\rho_E = (I \otimes W_{2,0}) \rho_W (I \otimes W_{2,0}^+) + (I \otimes W_{2,1}) \rho_W (I \otimes W_{2,1}^+)
\]

or

\[
\sigma_E = (I \otimes W_{2,0}) \sigma_W (I \otimes W_{2,0}^+) + (I \otimes W_{2,1}) \sigma_W (I \otimes W_{2,1}^+)\]
After receiving the system $B$, Bob applies reverse weak measurement with the Kraus operator given by Eq. (6). The final shared state becomes either

$$\rho_R = (I \otimes N_{2,0}) \rho_E (I \otimes N_{2,0}^\dagger),$$

or

$$\sigma_R = (I \otimes N_{2,0}) \sigma_E (I \otimes N_{2,0}^\dagger).$$

Bob chooses the strength of the reverse weak measurement $q_2$ such that it maximizes the violation of the steering inequality (7) and hence, it maximizes the key rate given by Eq. (8).

When Alice prepares systems $A$ and $B$ either in the state $|\psi^{\pm}\rangle$ or in the state $|\phi^{\pm}\rangle$ given by Eq. (9), the left-hand side of the inequality (7) becomes

$$\frac{1}{2} [P(b_{\sigma_x}|a_{A_1}) + P(b_{\sigma_z}|a_{A_1})] = \frac{3}{4} + \frac{3}{4\sqrt{1+D_2-D_2p_2}}$$

where Alice’s measurement settings are the same as the measurement settings when the technique of weak measurement is not applied, i.e., $\{\sigma_x, \sigma_z\}$, and the optimal strength of the reverse weak measurement is given by $q_2^O = \frac{2D_2+p_2-2D_2p_2}{1+D_2-D_2p_2}$. The lower bound of key rate is given by

$$r_R^L = \log_2 \left[ \frac{3 + \frac{3}{4\sqrt{1+D_2-D_2p_2}}}{\frac{3}{4} + \frac{3}{4\sqrt{1+D_2-D_2p_2}}} \right],$$

where the success probability of achieving this bound is the probability of sharing the state $\rho_R^I$, i.e., $Tr[\rho_R^I] = (1 - D_2)(1 - p_2)$. In Fig. 3, we compare the key rate (13) without using the technique of weak measurement with the key rate (25) when the technique of weak measurement and its reversal is used. From this figure it is clear that one can protect steerability and hence, the key rate of 1s-DIQKD from decoherence modeled by ADC.

**Case II.** Here both the systems $A$ and $B$ interact with the environment via ADC. To protect the correlation from decoherence, Alice makes weak measurements on both systems. When both systems are not detected, the combined state of system $A$ and $B$ is either given by

$$\rho_W’ = (M_{1,0} \otimes M_{2,0}) \rho^\pm_{AB} (M_{1,0} \otimes M_{2,0}^\dagger),$$

or

$$\sigma_W’ = (M_{1,0} \otimes M_{2,0}) \sigma^\pm_{AB} (M_{1,0} \otimes M_{2,0}^\dagger).$$

Next, Alice sends the system $B$ to Bob and allows both systems to interact with the environment. Due to the environmental effect, the shared state becomes either

$$\rho_E’ = (W_{1,0} \otimes W_{2,0}) \rho_W’ (W_{1,0}^\dagger \otimes W_{2,0}^\dagger),$$

$$+ (W_{1,0} \otimes W_{2,1}) \rho_W’ (W_{1,0}^\dagger \otimes W_{2,1}^\dagger),$$

$$+ (W_{1,1} \otimes W_{2,0}) \rho_W’ (W_{1,1}^\dagger \otimes W_{2,0}^\dagger),$$

$$+ (W_{1,1} \otimes W_{2,1}) \rho_W’ (W_{1,1}^\dagger \otimes W_{2,1}^\dagger).$$

At the end, both apply reverse weak measurement having Kraus representation given by Eq. (6). The final shared state either becomes

$$\rho_R’ = (N_{1,0} \otimes N_{2,0}) \rho_E’ (N_{1,0} \otimes N_{2,0}^\dagger),$$

or

$$\sigma_R’ = (N_{1,0} \otimes N_{2,0}) \sigma_E’ (N_{1,0} \otimes N_{2,0}^\dagger).$$

Now, we study the steerability of the shared states $\rho_R’$ ($\sigma_R’$). When Alice prepares systems $A$ and $B$ in the state $|\psi^{\pm}\rangle$, the choice of the set of observables for Alice is the same as the settings used when both systems interact with environment and the technique of weak measurements is not applied, i.e., $\{A_1 = \sigma_z, A_2 = \sqrt{1-D_2} \sigma_x - D_2 \sigma_z\}$. Here, for simplicity, we consider both systems interact with equal strength with the environment, i.e., $D_1 = D_2 = D$, and the same strength of weak measurement and reverse weak measurement is used for both systems, i.e., $p_1 = p_2 = p$ and $q_1 = q_2 = q$. We numerically maximize the quantity $\frac{1}{2} [P(b_{\sigma_x}|a_{A_1}) + P(b_{\sigma_z}|a_{A_1})]$ with respect to the strength of the reverse weak measurement $q$. In Fig. 4, we display the improvement of key rate when Alice prepares the systems in the state $|\psi^{\pm}\rangle$. For the prepared state $|\phi^{\pm}\rangle$, the improvement of the key rate using weak measurement is not possible.

As this technique is associated with weak measurement, the success probability of sharing the final state $\rho_R’$ ($\sigma_R’$) is given by $\max_q [Tr[\rho_R]]$ (max_q [Tr[\sigma_R]]). Hence
The lower bound of key rate is plotted against the strength of decoherence $D_1 = D_2 = D$ (x-axis) and the strength of weak measurement $p_1 = p_2 = p$ (y-axis). The upper surface is for the key rate is for the state $|\psi^{\pm}\rangle$ given by Eq. (9), using the technique of weak measurement, and the lower one is for the key rate given by Eq. (13).

Finally, we calculate the average steerability of the state $\rho'_R$, where the average is taken over the success probability of sharing the state $\rho'_R$. Thus, the relevant quantity which provides the lower bound to the average key rate depending upon the success probability is given by

$$\max_q \left[ T[r'] \right] \max_q \left[ \frac{1}{2} [P(b_\sigma | a_{A_1}) + P(b_{\sigma'} | a_{A_2})] \right] + (1 - \max_q \left[ T[r'] \right])^{3/4},$$

where $3/4$ is the upper bound of the steering relation (7), achievable with the help of an LHS model. Fig. (5) shows the improvement in the average key rate corresponding to the shared state $\rho'_R$. We see that the technique of weak measurement allows improvement of the average key rate in a notable region of parameter space.

The upper bound of the steering relation (7), achievable with the help of an LHS model. The improvement of the average key rate is possible for a range of values of the strength of decoherence and weak measurement.

VI. CONCLUSIONS

To summarize, in the present work we have discussed the effect on steerability and the key rate of the 1s-DIQKD protocol when the system possessed by one or both the parties interact with the environment through an amplitude damping channel. It is known from earlier studies that for a particular set of bipartite states having teleportation fidelity just below the quantum region, amplitude damping decoherence can improve the teleportation fidelity above the quantum region [11, 12]. This happens due to the enhancement of classical correlations as a consequence of environmental interaction on both the parties. However, we show here that amplitude damping decoherence is unable to improve the key rate whose upper bound is fixed by steerability of bipartite states, a quantum correlation that falls down with the strength of interaction with the environment.

Next, we use the technique of weak measurement to protect quantum steerability and the key rate in the presence of amplitude damping decoherence. We show that when one of the parties of a bipartite system interacts with the environment, one can protect the secret key rate in 1s-DIQKD with the help of weak measurement and its reversal for any maximally entangled state. However, when both systems interact with environment, the technique of weak measurement can protect the key rate only for prepared states of the type $|\psi^{\pm}\rangle$. Similar to the case of improvement of the teleportation fidelity [13], the technique of weak measurement fails to protect the key rate for prepared states of the type $|\phi^{\pm}\rangle$. The technique of weak measurement is associated with a success probability, as it is implemented with post-selection discarding the state when it is detected. We further show here, that considering even the unsuccessful attempts (when the systems are discarded), the average key rate turns out to be greater than the case where the weak measurement technique is not applied, for a considerable range of the interaction parameters.
