Abstract
We report a study of the magnetic and electronic properties of the non-centrosymmetric half-Heusler antiferromagnet HoPdBi ($T_N = 2.0$ K). Magnetotransport measurements show HoPdBi has a semimetallic behavior with a carrier concentration $n = 3.7 \times 10^{18}$ cm$^{-3}$ extracted from the Shubnikov–de Haas effect. The magnetic phase diagram in the field-temperature plane has been determined by transport, magnetization, and thermal expansion measurements: magnetic order is suppressed at $B_M \sim 3.6$ T for $T \to 0$. Superconductivity with $T_c \sim 1.9$ K is found in the antiferromagnetic phase. Ac-susceptibility measurements provide solid evidence for bulk superconductivity below $T_c = 0.75$ K with a screening signal close to a volume fraction of 100%. The upper critical field shows an unusual linear temperature variation with $B_c2(T \to 0) = 1.1$ T. We also report electronic structure calculations that classify HoPdBi as a new topological semimetal, with a non-trivial band inversion of 0.25 eV.

Keywords: superconductivity, antiferromagnetism, topological insulators

1. Introduction

The compound HoPdBi is a member of the large family of half-Heuslers that crystallize in the non-centrosymmetric space group $F\overline{4}3m$ \cite{1}. Ternary Heuslers with composition 2:1:1 and half Heuslers with composition 1:1:1 attract ample attention because of their flexible electronic structure, which gives rise to applications as multifunctional materials in, for example, the fields of spintronics and thermoelectricity \cite{2}. Recently, a new incentive to investigate half-Heusler compounds was provided by first principles calculations \cite{3-5}. By employing the hybridization strength and the magnitude of the spin–orbit coupling it was established that ‘heavy-element’ half-Heusler compounds may show a non-trivial band inversion, similar to the prototypical topological insulator HgTe \cite{6-8}. Topological half-Heuslers are zero-gap semiconductors, where the topological surface states can be created by applying strain that opens the gap. The emergence of magnetic order and superconductivity at low temperatures in half-Heuslers provides a new research direction to study the interplay of topological states, superconductivity, and magnetic order \cite{9}.

Recently, much research has been devoted to the band-inverted half-Heusler platinum and palladium bismuthides, notably because some of these superconduct at low temperatures \cite{10}: LaPtBi ($T_c = 0.9$ K \cite{11}), YPtBi ($T_c = 0.77$ K \cite{12, 13}), LuPtBi ($T_c = 1.0$ K \cite{14}) and LuPdBi ($T_c = 1.7$ K \cite{15, 16}). The $s$-$p$ inverted band order ($\Gamma_8 > \Gamma_6$) makes these...
compounds candidates for topological superconductivity [17, 18]. Topological superconductors are predicted to be unconventional superconductors, with an admixture of even- and odd-parity Cooper pair states in the bulk, and protected Majorana states at the surface [7, 8]. Since the crystal structure lacks inversion symmetry these superconductors might also be classified as non-centrosymmetric. Here theory predicts a mixed even- and odd-parity Cooper pair state [19] as well.

Recently, we reported the observation of superconductivity ($T_c = 1.22$ K) and antiferromagnetic order ($T_N = 1.06$ K) in the half-Heusler ErPdBi [9]. In addition, electronic structure calculations predicted a sizeable band inversion, which makes ErPdBi a first candidate for the investigation of the interplay of topological states, superconductivity, and magnetic order. Another candidate proposed is CePdBi ($T_c = 1.3$ K, $T_N = 2.0$ K), however, here superconductivity develops in a small part of the sample and is associated with a disordered phase [20]. The coexistence of superconductivity and magnetic order in ErPdBi provided a strong motivation to search for similar phenomena in other REPdBi compounds (RE = Rare Earth), such as HoPdBi [1, 21]. HoPdBi was reported to be an antiferromagnet with a Néel temperature $T_N = 2.2$ K [21]. Its magnetic susceptibility follows a Curie–Weiss law with an effective moment $\mu_{\text{eff}} = 10.6 \mu_B$, in good agreement with the theoretical value for free RE$^{3+}$ ions with Russell-Saunders coupling ($J = 8$). The weak antiferromagnetic coupling is furthermore inferred from the low value of the Curie–Weiss constant $\Theta = -6.4$ K. Here we report the results of transport, magnetic, and thermal measurements on single crystalline HoPdBi. Our flux-grown crystals show antiferromagnetic order at $T_N = 2.0$ K and superconductivity at $T_c \sim 1.9$ K. However, the transition to bulk superconductivity, inferred from the full diamagnetic screening signal (100% volume fraction), sets in near $T^{\text{bulk}} \sim 0.75$ K. We report the magnetic and superconducting phase diagram in the field-temperature plane, as well as electronic structure calculations that reveal a non-trivial band inversion of 0.25 eV at the gamma point. In the course of our investigations, Nakajima et al. [22] reported that superconductivity occurs in almost the entire antiferromagnetic REPdBi series, with $T_c \sim 1$ K for HoPdBi.

2. Methods

Several single crystalline batches of HoPdBi were prepared using Bi flux. The high purity elements Ho, Pd, and Bi (purity 3N5, 4N, and 5N, respectively) served as starting material. First an ingot of HoPdBi was prepared by arc-melting and placed in an alumina crucible with excess Bi flux. The crucible was sealed in a quartz tube under a high-purity argon atmosphere (0.3 bar). Next the tube with the crucible was heated in a furnace to 1150 °C and kept at this temperature for 36 h. Then the tube was slowly cooled to 500 °C at a rate of 3 °C per hour to form the crystals. The single-crystalline nature of the crystals was checked by Laue backscattering. After cutting the crystals in suitable shapes for the various experiments, the surfaces were cleaned by polishing. Powder x-ray diffraction confirmed the F43m space group and the extracted lattice parameter, $a = 6.605$ Å, is in good agreement with the literature [1]. Several tiny extra diffraction lines point to the presence of a small amount of an impurity phase (< 5%). These lines could not be matched to potential inclusions or impurity phases, such as Bi, PdBi, $\alpha$-Bi$_2$Pd and $\beta$-Bi$_2$Pd. The results presented here are taken on samples that all come from the same single-crystalline batch. The measured samples are labeled #2–#4, and show very similar magnetic and superconducting properties.

Magnetic and transport measurements were carried out in a Physical Property Measurements System (PPMS, Quantum Design) in the temperature range 1.8–300 K. The magnetization and susceptibility were measured utilizing a Vibrating Sample Magnetometer, while the resistance and Hall effect were measured using a standard four-point low-frequency ac-technique with an excitation current of 1 mA. The specific heat was measured down to 2.0 K on a crystal with a mass of 10 mg in the PPMS as well. Low temperature, $T = 0.24 – 10$ K, resistance and ac-susceptibility measurements were made in a $^3$He refrigerator (Heliox, Oxford Instruments) using a low-frequency lock-in technique with low excitation currents ($I \leq 200 \mu$A). The coefficient of linear thermal expansion, $\alpha = L^t / (Ld/DT)$, with $L$ the sample length, was measured using a three-terminal parallel-plate capacitance method using a home-built sensitive dilatometer based on the design reported in [23]. Magnetoresistance data were taken in a dilution refrigerator (Kelvinox, Oxford Instruments) for $T = 0.03–1$ K and high magnetic fields up to 17 T. Additional low-temperature dc-magnetization and ac-susceptibility measurements were made using a SQUID magnetometer, equipped with a miniature dilution refrigerator, developed at the Néel Institute.

3. Results and analysis

3.1. Superconductivity

In figure 1 we show the resistivity $\rho(T)$ of a single crystal of HoPdBi (sample #2). The resistivity values are rather large and $\rho(T)$ has a broad maximum around 80 K. The charge carrier concentration $n_h$ extracted from the low field ($B < 2$ T) Hall effect measurements is traced in the inset of figure 1. The carriers are holes and at the lowest temperature ($T = 2.0$ K) $n_h = 1.3 \times 10^{19}$ cm$^{-3}$. These transport parameters reveal semimetallic-like behavior. At low temperatures, the resistivity drops to zero, which signals the superconducting transition.

The superconducting transition measured by resistivity in zero and applied magnetic fields is reported in detail in figure 2. The superconducting transition at $B = 0$ is fairly broad, with an onset temperature of 2.3 K and zero resistance at 1.6 K. By tracing the maximum in the derivative $d\rho/dT$ we obtain $T_c = 1.86$ K. The broad transition is most likely related to the simultaneous development of antiferromagnetic order with $T_N = 2.0$ K (see below). A similar rounded $\rho(T)$ near the onset for superconductivity was observed for ErPdBi, where $T_c \approx T_N$ as well [9]. We have determined the upper critical field $B_{c2}$ by taking $T_c(B)$ as the maximum in $d\rho/dT$ obtained in constant magnetic fields. See the inset of figure 2 for the data at $B = 1.0$ T. Here the structure at 2.0 K signals the antiferromagnetic transition. The temperature variation $B_{c2}(T)$ is
reported in the phase diagram, figure 7. In the upper inset of figure 2 we show the zero-field data for sample #3. The resistivity data for this sample (data in field are not shown) are in good agreement with the results obtained for sample #2.

In figure 3 we show ac-susceptibility (\( \chi_{ac} \)) data taken on sample #3 for different driving fields \( B_{ac} \) ranging from 0.0025 to 0.25 mT. Upon cooling \( \chi_{ac} (T) \) first increases and has a pronounced maximum at 2.0 K, which locates the antiferromagnetic phase transition temperature. Upon further cooling a large superconducting signal appears below 0.75 K. For the smallest driving fields \( B_{ac} \leq 0.05 \) mT the screening fraction associated with this diamagnetic signal is \(~90\%\), which provides strong support for bulk superconductivity. Upon increasing the driving field to 0.25 mT the magnitude of the diamagnetic signal is rapidly depressed, which indicates the lower critical field \( B_{c1} \) is very small. However, a close inspection of the data shows that a weaker diamagnetic signal develops near 1.8 K, which is close to the midpoint of the superconducting transition at 1.9 K.

3.2. Antiferromagnetic order

Magnetic susceptibility measurements carried out in a field of 0.1 T confirm local moment behavior of the Ho moments. For \( T > 50 \) K Curie–Weiss behavior is observed with an effective moment \( \mu_{eff} = 10.3 \) \( \mu_B \) and a negative Curie–Weiss constant \( \Theta_p = -5.7 \) K indicating the presence of antiferromagnetic interactions. These values are close to the ones reported in [21]. In figure 4 we show the dc-susceptibility around the antiferromagnetic transition measured in fields up to 3 T down to very low temperatures (0.1 K). The Néel temperature is progressively shifted with field and can no longer be discerned at the largest field. The variation \( T_N (B) \) is traced in the phase diagram (figure 7). In the right panel we show the magnetization measured at \( T = 0.075 \) K, deep in the antiferromagnetic phase, and at 2 K and 5 K, measured along the [1 0 0] axis. At the lowest temperature the magnetization increases rapidly until it reaches a value of \(~6 \) \( \mu_B \) at 3 T, after which the increase is more gradual. In a field of 8 T the magnetization attains a value of 7.2 \( \mu_B \) which is still considerably below the saturation value \( m_s = gJ = 10 \) \( \mu_B \) (here \( g = 5/4 \) is the Landé factor). An explanation for this is offered by the sizeable magnetic anisotropy associated with the Ho ions (see section 4). The presence of magnetocrystalline anisotropy can also be inferred from the very weak signature of a metamagnetic-like transition observed in \( M (B) \) below \( T_N \).
Around the antiferromagnetic transition. Upon cooling \( F_2 \) a broad magnetic contribution centered around \( J \) showing the Shubnikov–de Haas effect at 0.075, 2.0 and 5.0 K. A fast Fourier transform extracted from the thermal expansion is traced in figure 5. Here the

\[
\frac{\Delta p}{p} = \frac{\Delta \rho}{\rho} \quad \text{at } T = 0.05 \text{ K.}
\]

In the lower inset of figure 6 we trace the resulting oscillations. In the cubic symmetry, the holmium ground state. In the cubic symmetry, the holmium associated with the partial lifting of the crystalline electric field is most likely a Schottky contribution to the specific heat. We remark that the magnetic susceptibility

\[
\chi(T) = \frac{\rho}{B} \quad \text{for } T \leq 50 \text{ K.}
\]

The solid line indicates the Weiss behavior below 50 K as well. By combining the thermal expansion and specific heat data we can make an estimate of the pressure variation of \( T_N \) using the Ehrenfest relation

\[
dT_N/dp = V_n \Delta \beta / (\Delta c/T_N).
\]

Here the coefficient of volume expansion \( \beta = 3\alpha_0 \) and

\[
V_n = 4.3 \times 10^{-5} \text{ m}^3 \text{ mol}^{-1}
\]

is the molar volume. Using the experimental values

\[
\Delta \alpha = 1.2 \times 10^{-4} \text{ K}^{-1} \quad \text{and } \Delta c/T_N = -5 \text{ J} \text{ mol}^{-1} \text{ K}^{-1},
\]

we obtain

\[
dT_N/dp = -0.3 \text{ K kbar}^{-1}.\]

In an applied field, the longitudinal thermal expansion measured along the direction of the magnetic field, \( \alpha_l \) develops a pronounced minimum. The negative \( \alpha_l \) indicates a large magnetocrystalline anisotropy, with an expansion along the field and a contraction perpendicular to the field, upon cooling below \( T_N \). Notice, in magnetic field \( \beta = \alpha_l + 2\alpha_0 \). The variation \( T_N(B) \) extracted from the thermal expansion is traced in the phase diagram figure 7.  

3.3. Quantum oscillations

The magnetoresistance was measured in magnetic fields up to 17 T at low temperatures in the dilution refrigerator. A typical trace taken at \( T = 0.05 \text{ K} \) is shown in figure 6. After the suppression of superconductivity, the kink at \( B_d = 3.6 \text{ T} \) locates the antiferromagnetic phase boundary. In fields exceeding 8 T we observed Shubnikov–de Haas oscillations. Since the oscillatory component is rather small (\( \Delta p/p \approx 0.1 \% \) ) and superimposed on a non-monotonic background, it is difficult to extract the precise magnitude as a function of \( 1/B \). In the lower inset of figure 6 we trace the resulting oscillations in \( \Delta \rho \) as a function of \( 1/B \). A fast Fourier transform (upper inset) shows the frequency is 75 ± 5 T. For a circular extremal cross section

\[
A_s(E_F) = \pi k_F^2
\]

we calculate with help of the Onsager relation a Fermi wave vector

\[
k_F = 4.8 \times 10^8 \text{ m}^{-1}
\]

Assuming a spherical Fermi surface pocket, the corresponding 3D carrier density

\[
n = k_F^3/3\pi^2 = 3.7 \times 10^{18} \text{ m}^{-3}
\]
which is a factor ~3.5 smaller than the value deduced from the Hall effect measurements. Additional measurements at $T = 0.3$ and 0.6 K show the thermal damping is very weak, which points to an effective mass much smaller than the free electron mass, $m_{\text{eff}} < 0.5m_e$, as reported for other topological semimetals [12, 25].

3.4. Phase diagram

In figure 7 we present the magnetic and superconducting phase diagram of HoPdBi. The upper critical field $B_{c2}$ shows a smooth variation with temperature and extrapolates to the value of 1.1 T at $T = 0$. This tells us $B_{c2}(T)$ is associated with the superconducting transition observed at 1.9 K in a zero field. When we compare the $B_{c2}$-data to the Werthamer–Helfand–Hohenberg (WHH) curve for a weak-coupling spin-singlet orbital-limited superconductor, some departure appears below ~0.7 K. We remark this is close to the temperature below which the diamagnetic screening signal shows the sudden increase towards bulk superconductivity (see figure 2). In the WHH model the clean-limit zero-temperature orbital critical field can be calculated from the relation $B_{c2}^{\text{orb}}(0) = 0.72 \times T_c^2 \frac{dB_{c2}}{dT}|_{T_c}$ and attains a value of 0.9 T (in the dirty limit the coefficient 0.72 is replaced by 0.69). From the experimental value $B_{c2}(0) = 1.11$ T we calculate, utilizing the relation $B_{c2} = \Phi_0/2\pi\xi^2$, where $\Phi_0$ is the flux quantum, a superconducting coherence length $\xi = 17$ nm. A departure from the WHH model has also been observed for ErPdBi [9] and notably for YPtBi [12, 13], where it was taken as a strong indication of an odd-parity component in the superconducting order parameter. We remark that the superconducting phase is completely embedded in the antiferromagnetic phase.

The antiferromagnetic phase boundary has been determined by resistivity, magnetization and thermal expansion measurements, see figure 7. After an initial ($B < 1$ T) steep increase with field, $T_N$ smoothly decreases, and the antiferromagnetic phase transition is suppressed at $B_{c2}(0) = 3.6$ T. Values for $T_N$ extracted from the magnetization and thermal expansion are somewhat lower than the values obtained by transport, but all three experiments track the same phase boundary. These differences might be partly attributed to different orientations of the crystals in the magnetic field in connection to the large magnetic anisotropy. For the magnetization experiments the magnetic field was applied along [1 0 0], while for the other experiments the field was applied along an arbitrary crystal direction. In the figure we compare the phase boundary with the phenomenological order parameter function $B_{c2}(T) = B_{c2}(0)(1 - (T/T_N)^\beta)^\alpha$ with $T_N = 2.0$ K, $B_{c2}(0) = 3.6$ T, $\alpha = 2$ and $\beta = 0.34$. The latter value is close to the theoretical value $\beta = 0.38$ expected for a 3D Heisenberg antiferromagnet [26].

3.5. Electronic structure

To understand the electronic properties, we have performed ab initio band structure calculations [27] based on the density-functional theory. The core electrons are represented by the projector-augmented-wave potential. We keep only three valence electrons of Ho (equivalent to La) and freeze all other $f$ electrons as core electrons to simplify the understanding of the topology. The calculated bulk band structure of HoPdBi exhibits a zero-gap, and is quite similar to that of ErPdBi [9] and other half-Heusler topological semimetals [3, 4]. The $\Gamma_6$ band (contributed by Pd-$s$ states) is below the $\Gamma_5$ bands, showing the hallmark of band inversion. Therefore, we can clearly conclude that HoPdBi is also a topological semimetal. The effect of magnetization of Ho-$f$ states is expected to possibly split the spin degeneracy slightly, but to preserve the inverted band order because the band inversion strength (the energy difference between the $\Gamma_5$ and $\Gamma_6$ bands) is as large as ~0.25 eV. The measured sample is slightly $p$-doped, which will cause $\varepsilon_F$ to lie marginally below zero.

4. Discussion

Our systematic transport, magnetic, and thermal properties study demonstrates that HoPdBi combines local moment magnetism and superconductivity and thus behaves in a very similar way to the related half-Heusler compound ErPdBi [9]. Superconductivity occurs at $T_c = 1.9$ K as determined by the resistive transition and the onset in $\chi_{ac}$; however, the transition to a full diamagnetic screening fraction sets in at a lower temperature, near 0.75 K. These results are in line with the recent work by Nakajima et al [22], but nevertheless there are some noticeable differences: the midpoint of the resistive transition...
is at \( \sim 1.0 \text{ K} \), and the onset of the diamagnetic signal is at \( \sim 0.9 \text{ K} \) [22]. Moreover, the transition measured by \( \chi_{ac} \) [22] is very broad and extends to the lowest temperature measured \( (\sim 0.1 \text{ K}) \). A comparison of both studies suggests the superconducting phase transition found below \( \sim 0.9 \text{ K} \) by Nakajima et al [22] is to be associated with the transition to the bulk superconducting state at 0.75 K, as reported in figure 2. The presence of a small volume fraction of our sample that superconducts at 1.9 K remains a puzzling aspect. A possible explanation is the presence of an impurity phase. Among the binary Bi-Pd alloys \( \alpha \)-Bi\(_{2}\)Pd is reported to superconduct at 1.7 K [28]. However, the few extra tiny lines in the diffraction pattern could not be matched to the structure of \( \alpha \)-Bi\(_{2}\)Pd. Moreover, \( B_{c2}(0) \) of \( \alpha \)-Bi\(_{2}\)Pd is small [22], which is at variance with the measured value \( B_{c2}(0) = 1.1 \text{ T} \).

A second, appealing explanation for superconductivity at 1.9 K is the occurrence of surface superconductivity associated with the topological surface states. Surface superconductivity at temperatures higher than the bulk \( T_c \) was recently proposed by Kapitulnik et al [29, 30] for the topological half-Heuslers YPtBi and LuPtBi. Experimental evidence for this was provided by (surface sensitive) Scanning Tunneling Spectroscopy measurements. Surface superconductivity may also offer an explanation for the ‘unknown impurity phase’ with \( T_c = 1.7 \text{ K} \), i.e. above the bulk \( T_c \) of 1.2 K, reported for ErPdBi [9]. Interestingly, Nakajima et al [22] claim that surface superconductivity with \( T_c = 1.6 \text{ K} \) can be induced by heat treatments at 200 °C for all REPdBi. These results may open a new, fascinating research direction in the field of topological superconductivity. Future experiments have to be directed to disentangle surface and bulk superconductivity in order to put these ideas on a firmer footing.

**Figure 8.** Calculated bulk band structure of the half-Heusler HoPdBi. The projection of the Pd-s states is highlighted by the thickness of the solid red lines. The bands \( \Gamma_{7,8} \) are labeled according to the Fermi energy. \( E_F \) is shifted to zero (horizontal dashed line). The measured sample is slightly \( p \)-doped, which will cause \( E_F \) to lie marginally below zero.

Local-moment antiferromagnetic order has been detected for most members of the REPdBi series [9, 21, 22, 31], with \( T_N \) following the de Gennes scaling: \( T_N \propto g_J^2(J^2(J+1)) \) with \( g_J \) the Landé factor (see e.g. [32]). The Neél temperature \( T_N = 2.0 \text{ K} \) of our crystals is in between the values 2.2 K and 1.9 K reported in [21] and [22], respectively. The phase diagram (figure 7) shows that antiferromagnetic order entirely encloses the superconducting phase. Superconductivity is attributed to the \( \Gamma_8 \) hole states (see figure 8). Normally, conventional BCS spin-singlet superconductivity is suppressed by local-moment magnetism. However, in HoPdBi the energy scales are comparable, since \( T_N \geq T_N \). The large superconducting volume fraction inferred from the low temperature \( \chi_{ac} \) and dc-magnetization measurements indicates that superconductivity and antiferromagnetic order coexist. Magnetic local-probe techniques, such as muon spin rotation/relaxation (\( \mu \)SR) and/or nuclear magnetic resonance (NMR) would be very helpful to verify the coexistence of both ordering phenomena on the microscopic scale. From recent neutron diffraction experiments [22] it was concluded that HoPdBi has a type-II antiferromagnetic structure: ferromagnetic planes couple antiferromagnetically with a propagation vector along the cube diagonal, \( Q = (0.5, 0.5, 0.5) \). The magnetization curves (figure 4) and the thermal expansion in field (figure 5) reveal the magnetocrystalline anisotropy is rather strong. This offers the following scenario for the magnetization curves. When the field is increased along the \( [1 0 0] \) axis the spins progressively reorient towards the field, while still pointing along the \( [1 1 1] \) direction. Near the antiferromagnetic phase boundary the component of the spin along the \( [1 0 0] \) direction is \( m_s/\sqrt{3} = 5.8 \mu_B \), which is close to the experimental value. For fields above 3 T the spins are being pulled against the anisotropy field, which explains the reduced value with respect to \( m_s = 10 \mu_B \). Interestingly, theoretical work based on symmetry classifications predicts the type II antiferromagnetic structure in these half-Heuslers produces a new ground state: an antiferromagnetic topological insulator [33].

Recently, it was proposed that a first realization of this novel electronic state is found in the half-Heusler antiferromagnet GdPtBi (\( T_N = 9 \text{ K} \)) [34].

The large contribution of antiferromagnetic order to the thermal properties (figure 5) hampers the detection of superconductivity in the thermal expansion and specific heat. An estimate for the step-size \( \Delta \gamma \) in the specific heat at \( T_c \) can be calculated from the standard BCS relation \( \Delta c/T_c < 1.43 \), where \( \gamma \) is the Sommerfeld coefficient. It appears that \( \gamma \) cannot reliably be deduced from the experimental data (see figure 5) because of the presence of the large magnetic contribution centered around 15 K. However, an estimate for \( \gamma \) can be obtained from the Shubnikov–de Haas data using the relation

\[
\gamma = \frac{\pi^2 k_B^2}{m^* c^2} / 3 \text{, where } g(E_F) = m^* k_B / h^2 \pi^2 \text{ is the density of states.}
\]

With the parameters calculated in section 3.3 we obtain

\[
\gamma < 0.1 \text{ mJ molK}^{-2} \text{ and } \Delta c < 0.1 \text{ mJ K}^{-1} \text{ at } T_c, \text{ which is very small indeed. An estimate for the step size in the thermal expansion coefficient, } \Delta c, \text{ at } T_c \text{ can be obtained from the}\]

Ehrenfest relation \( dT_c / d\rho = V_p 3\alpha / (\Delta c/T_c) \). Assuming a typical
value for $\frac{dT_c}{dp} = 0.044$ K GPa$^{-1}$ [13] we calculate $\Delta \alpha$ at $T_c$ is smaller than $4.5 \times 10^{-11}$ K$^{-1}$, which is beyond the resolution of the dilatometer.

The occurrence of superconductivity in a Ho-based compound is uncommon. Rare examples are found among the Chevrel phases [35] and the heavy-rare earth cuprates [36] and pnictides [37]. The coexistence of superconductivity and antiferromagnetic order is found in the borocarbide HoNi$_2$B$_2$C [38], but here $T_c = 10.5$ K and exceeds $T_N = 6.0$ K. An important new aspect in the REPdBi series is the non-centrosymmetric crystal structure and the topological nature of the electronic structure. This provides a new opportunity to investigate unconventional superconductivity, due to mixed even and odd parity Cooper pair states, and its interplay with long-range magnetic order.

5. Summary

We have investigated the transport, magnetic, and thermal properties of the half-Heusler antiferromagnet HoPdBi. Electrical resistivity and ac-susceptibility data taken on flux-grown single crystals show superconductivity occurs below 1.9 K. We demonstrate HoPdBi is a bulk superconductor. However, the transition to bulk superconductivity, as indicated by a diamagnetic screening fraction close to 100%, sets in at a lower temperature of 0.75 K. The Néel temperature $T_N$ is 2.0 K as determined by thermal expansion and dc-magnetization measurements. The superconducting and magnetic phase diagram in the $B - T$ plane has been determined: Superconductivity is confined to the antiferromagnetic phase. Electronic structure calculations show HoPdBi is a topological semimetal with a band inversion of 0.25 eV at the $\Gamma$-point. This is in line with the semimetallic behavior observed in the electrical resistivity and the low carrier concentration $n_p = 3.7 \times 10^{18}$ cm$^{-3}$ extracted from the Shubnikov–de Haas effect. We conclude, HoPdBi belongs to the half-Heusler REPdBi series with a topological band structure and presents a new laboratory tool to study the interplay of antiferromagnetic order, superconductivity and topological quantum states [9, 22].
