We find that a repulsive potential of graphene in the presence of a magnetic field has bound states that are peaked inside the barrier with tails extending over \(\ell(N + 1)\), where \(\ell\) and \(N\) are the magnetic length and Landau level(LL) index. We have investigated how these bound states affect scaling properties of the induced density of filled Landau levels of massless Dirac fermions. For chiral fermions we find, in strong coupling regime, that the density inside the repulsive potential can be greater than the value in the absence of the potential while in the weak coupling regime we find negative induced density. Similar results hold also for non-chiral fermions. As one moves from weak to strong coupling regimes the effective coupling constant between the potential and electrons becomes more repulsive, and then it changes sign and becomes attractive. Different power-laws of induced density are found for chiral and non-chiral fermions.

PACS numbers:

I. INTRODUCTION

Non-relativistic massless Dirac electrons exist in two-dimensional graphene layers near K and K' Brillouin points\(^1–4\). Energy dispersions form Dirac cones with conduction and valence bands meeting at the Dirac point. The wavefunction has two components: the first component gives the probability amplitude of finding the electron on A carbon atoms while the second component gives the amplitude of finding it on B carbon atoms. In the presence of a magnetic field the Dirac cones split into Landau levels with some unique features\(^5–8\). A Landau level with zero energy that is independent of magnetic field develops with chiral wavefunctions. Other non-chiral Landau levels of conduction and valence bands have opposite energies but their wavefunctions are identical except for phase factors\(^9, 10\). The energies of these Landau levels depend non-linearly on magnetic field

\[
E_N = \text{sgn}(N)E_m \sqrt{2|N|},
\]

where the energy separation between these LLs is set by \(E_m = \frac{\hbar v_F}{2\pi} R\). Valence band LLs are labeled \(N = -1, -2, -3, \ldots\) with decreasing energy, while conduction band LLs are labeled \(N = 1, 2, 3, \ldots\) with increasing energy. The zero energy LL has \(N = 0\).

These unusual graphene LLs respond rather differently to presence of potentials\(^13–16\) in comparison with LLs of ordinary semiconductors: Confinement and deconfinement transitions\(^13\) and bound states forming inside an antidot\(^16\) through complete Klein tunneling are predicted. Here we consider the electron density in the presence of a rotationally invariant and repulsive potential \(V(r)\) with strength \(V\) and range \(R\). The electron density of the \(N\)th filled LL is given by

\[
n_N(r) = \sum_{J \in \text{filled Landau level}} |\Psi_J N(r)|^2,
\]

where eigenstates \(\Psi_J N(r)\) and eigenvalues \(E_N(J)\) are labeled by LL index \(N\) and half-integer angular momentum quantum number \(J\). In the absence of a localized potential the dimensionless density takes the value \(\ell^2 n_N(r) = \frac{1}{2\pi}\). We define the induced density as the difference between densities with and without the potential

\[
\ell^2 \Delta n_N(r) = \ell^2 n_N(r) - \frac{1}{2\pi}.
\]

Graphene barrier has a natural energy scale, \(E_c = \frac{\hbar v_F}{2}\). It is interesting to note that the ratio between this energy scale and the energy scale of LLs is given by the ratio between two length scales of the problem:

\[
\frac{E_m}{E_c} = \frac{R}{\ell}.
\]

*corresponding author, eyang812@gmail.com
We find that the correct scaling function of the induced density has the form

$$\ell^2 \Delta n_N(r) = s_N (\frac{r}{R}, \frac{V}{E_c}, \frac{R}{\ell}).$$

It is different from the scaling function of ordinary LLs where one would expect that $\frac{V}{E_c}$ appears instead of $\frac{V}{E_m}$. In graphene $\frac{V}{E_m}$ does not contain non-perturbative effect of the formation of bound states in the barrier, and it cannot be used instead of $\frac{V}{E_c}$. Moreover, the variable $\frac{V}{E_m}$ is inappropriate since it becomes infinitely large at zero magnetic field (note $E_m = 0$ at $B = 0$), which leads to the unphysical result that the scaling function is independent of $V$.

The value of the dimensionless electron density at the center of the potential ($r = 0$) gives a good indication of how strong the effective coupling constant between the repulsive potential and electrons is. We will thus call this dimensionless induced density at $r = 0$, with sign change, as the effective coupling constant

$$\alpha_N (\frac{V}{E_c}, \frac{R}{\ell}) = -\ell^2 \Delta n_N(0) = -s_N (0, \frac{V}{E_c}, \frac{R}{\ell}).$$

As one moves from weak to strong coupling regimes the effective coupling constant becomes increasingly more repulsive, and then starts to decrease, passing through zero, and becomes attractive, see Figs.1 and 2. The strong, intermediate, and weak coupling regimes correspond to $\frac{R}{\ell} \ll 1$, $\frac{R}{\ell} \sim 1$, and $\frac{R}{\ell} \gg 1$, respectively. In the strong coupling regime a repulsive potential can effectively attract electrons, making the induced density positive. The physical origin of this effect is the formation of bound states that are peaked inside the barrier with tails extending over $\ell(N + 1)$. We stress that these states are not resonant states of the repulsive potential in graphene at $B=0$ [17,19] since the extent of the wavefunctions is finite and their energies form discrete spectra, unlike resonant states.

In the limit $V/E_c \ll 1$ we find the following power laws:

$$\ell^2 \Delta n_N(0) \approx (\frac{V}{E_c})^{\delta_N} g_N(R/\ell),$$

with $\delta_N = 2$ for the chiral $N = 0$ LL, but with $\delta_N = 1$ for non-chiral $N = 1$ LL. We find that $g_0(R/\ell)$ changes sign near 1. A plot of $g_0(R/\ell)$ is shown in Fig.2.

This paper is organized as follows. In Sec.II we present probability wavefunctions of boundstates in weak, intermediate, and strong coupling regimes. Using these probability wavefunctions we investigate scaling properties of induced densities for chiral and non-chiral fermions in Sec.III. We also compute the boundary between positive and negative values of induced densities in the parameter space. Summary and discussions are given in Sec.IV.

FIG. 2: Y-axis represents values of $g_0(R/\ell)$ obtained by data collapse for $N=0$ and $\frac{V}{E_c} < 0.7$. Note that this quantity is proportional to $-\alpha_N(\frac{V}{E_m}, R)$. Values $(R/\ell, V/E_c)$ used in the data collapse are shown in the inset. Note that the induced density changes sign near $R/\ell = 1$. Crosses represent the results obtained by treating $V(r)$ in the 2nd order perturbation theory. These results demonstrate that perturbative methods cannot be applied in the intermediate and strong coupling regimes.

II. MODEL CALCULATIONS OF EXACT WAVEFUNCTIONS

The electron density of a filled LL is computed from single electron wave functions, see Eq.(2). These wave functions are chosen to be eigenstates of the following model potential

$$V(r) = \begin{cases} V & r < R \\ 0 & r > R \end{cases}.$$  

In the strong coupling regime states with small values of $|J|$ are peaked near $r = 0$ and are particularly relevant for the density inside of the potential.

A. Energy spectrum

We compute eigenenergies $E_N(J)$ as a function of $J$ by solving Dirac equations. We choose the magnetic vector potential as $\vec{A} = \frac{B}{\ell} (-y, x, 0)$. The two-component wavefunctions of massless Dirac electrons obey the following Hamiltonian

$$H = v_F \vec{\sigma} \cdot (\vec{p} + \frac{e}{c} \vec{A}) + V(\vec{r})$$

where the Fermi velocity is $v_F$, the Pauli spin matrices are $\vec{\sigma} = (\sigma_x, \sigma_y)$. Eigenstates $\Psi_N^{(i)}(\vec{r})$ are also eigenstates of angular momentum operator

$$J_z = -i\partial_0 + \frac{\sigma_z}{2}.$$
where $\sigma_z$ is a Pauli spin matrix and $\theta$ is the polar angle. Since $J_z$ commutes with Dirac Hamiltonian of $N$th filled LL eigenstates must have the following form

$$\Psi_N^J(r, \theta) = e^{i(J-1/2)\theta} \begin{pmatrix} \chi_A(r) \\ \chi_B(r)e^{i\theta} \end{pmatrix} \tag{11}$$

with half-integer values of angular quantum number $J$. For each $N$ allowed values of $J$ are displayed in TABLE I. Some eigenenergies are shown in Fig.3. Although this spectrum resembles the spectrum of ordinary LLs[21] the wavefunctions of the eigenstates are rather different.

**B. Solutions in strong coupling regime**

It is instructive to study properties of probability wavefunctions in the strong coupling limit, where $R/\ell \to 0$. Eigenstates $(\chi_A, \chi_B)$ are determined by the pair of coupled first order differential equations

$$\begin{cases} -i\partial_x\chi_A + i\left[1\left(J - \frac{1}{2}\right) + \frac{1}{2}x\right]\chi_A = \epsilon(x)\chi_B \\ -i\partial_x\chi_B - i\left[1\left(J + \frac{1}{2}\right) + \frac{1}{2}x\right]\chi_B = \epsilon(x)\chi_A \end{cases}, \tag{12}$$

\begin{table}[h]

\begin{tabular}{|c|c|}
\hline
$J$ & $(n_i, m_i)$ \\
\hline
$\frac{1}{2}$ & (-3,1) \hspace{0.5cm} (-2,0) \hspace{0.5cm} (-1,0) \hspace{0.5cm} (0,0) \hspace{0.5cm} (1,0) \\
\hline
$\frac{1}{2}$ & (-3,2) \hspace{0.5cm} (-2,1) \hspace{0.5cm} (-1,1) \hspace{0.5cm} (0,1) \hspace{0.5cm} (1,1) \\
\hline
$-\frac{1}{2}$ & (-3,3) \hspace{0.5cm} (-2,2) \hspace{0.5cm} (-1,2) \hspace{0.5cm} (0,2) \hspace{0.5cm} (1,2) \\
\hline
$-\frac{1}{2}$ & (-3,4) \hspace{0.5cm} (-2,3) \hspace{0.5cm} (-1,3) \hspace{0.5cm} (0,3) \hspace{0.5cm} (1,3) \\
\hline
\end{tabular}
\caption{How $\chi_i^j$ and $\psi_{n,m}$ are related to each other. For a given $J$ some possible values of $(n, m)$ are listed. Empty boxes indicate that $(n, m)$ do not exist.}
\end{table}
shown in Fig. 4. Near the metric functions\[15\]. The obtained numerical results are obtained by solving the Dirac equations numerically using confluent hypergeometric functions\[10\]. The wavefunctions\[10\] for \( V/E \) are

\[
\psi_i(r) = \psi_{n,m}(r) = C_n \left( \frac{-\text{sgn}(n)i\phi_{|n|-1,m}(\bar{r})}{\phi_{|n|,m}(\bar{r})} \right) \quad (13)
\]

Here \( n \) and \( m \) are integers with \( m \geq 0 \). We define \( \text{sgn}(n) = -1, 0, 1 \) for \( n < 0, n = 0 \) and \( n > 0 \). The normalization constant \( C_n = 1 \) for \( n = 0 \) and \( C_n = 1/\sqrt{2} \) for \( n \neq 0 \). Applying angular momentum operator to Eq.\[13\] and comparing with Eq.\[11\] we find that the quantum numbers \( J \) and \( (n,m) \) are related to each other through

\[
J = |n| - m - 1/2. \quad (14)
\]

For a given value of \( J \) there are infinitely many possible values of \( (n,m) \), and we will order them with an index \( i \). How \((J,i)\) are related to \((n,m)\) is given in Table II. In Eq.\[13\] the wavefunctions \( \phi_{n,m}(\bar{r}) \) are the Landau level wavefunctions of ordinary two-dimensional systems\[22\].

\[
\phi_{n,m}(\bar{r}) = A_{n,m} \exp \left( \frac{i(n-m)\theta - r^2}{4\ell^2} \right) \left( \frac{r}{\ell} \right)^{|m-n|}
\times L_{(n+m-|m-n|)/2}^{|m-n|} \left( \frac{r^2}{2\ell^2} \right), \quad (15)
\]

where \( A_{n,m} \) are normalization constants.

To find solutions that are valid for all \( r \), we solve the Dirac equations numerically using confluent hypergeometric functions\[13\]. The obtained numerical results are shown in Fig. Inset: A (B) component is dashed (dotted) line.

![FIG. 4: Boundstates of strong coupling limit: \(|\Psi_{1/2}^{-1}(r)|^2\) for \( V/E_c = 1.82, R/\ell = 0.01, R = 1\text{mm}, V = 1.2\text{eV}\), and \( E = 0.009\text{eV}\). Inset: A (B) component is dashed (dotted) line.](image)

\[-i\Delta \chi_A = -i(\chi_A(R) - \chi_A(0)) \approx \epsilon(0) \int_0^{R/\ell} dx \chi_B \quad (16)\]

with \( \chi_B(0) = 0 \) and \( \epsilon(0) = (E - V)/E_m \). For \( J = 1/2 \) the properties are the opposite to those of \( J = 1/2 \): the B-component of the wavefunction \( \chi_B(x) \) peaked at \( x = 0 \) while A-component is peaked at \( x = R/\ell \). The amount of jump between 0 and \( R \) is

\[-i\Delta \chi_B \approx \epsilon(0) \int_0^{R/\ell} dx \chi_A. \quad (17)\]

In the strong coupling regime \( R/\ell < 1 \) probability wavefunctions can be significant inside the potential, see Fig. These states are peaked inside the potential range \( R \) and have tails extending over the length of order \( \ell(N + 1) \). Examples of such states with \( N = 0, 1, 2 \), and 3 are displayed in Fig. As \( N \) increases the extend of \( |\Psi_{N}^{-1/2}(r)|^2 \) outside the potential increases approximately as \( \ell(N + 1) \). However, the strength of peak within the range \( R \) decreases with increasing \( N \). We stress that these states are not resonant states of the repulsive potential since the extend of the wavefunctions is finite and their energies form discrete spectra, unlike resonant states. States shown in Fig contribute to a positive induced charge since the probability of finding an electron inside the potential has increased compared to the probability in the absence of the potential. This is a non-trivial effect of the interplay between effects of quantization of LL and Klein tunneling\[23, 24].

C. Solutions in intermediate and weak coupling regimes

We show how probability wavefunctions change as \( R/\ell \) changes from weak to intermediate coupling regimes. In the perturbative regime \( R/\ell \gg 1 \) the exact probability wavefunction at \( r = 0 \) is smaller than that of the unperturbed probability wavefunction, as shown in Fig.\[a\]. Note that cusps in the wavefunctions are negligible. Fig.\[b\] displays the exact probability wavefunctions \( |\Psi_0^{-1/2}(r)|^2 \) in the intermediate regime of \( R/\ell \sim 1 \). Both A and B components of it have cusps at \( r = R \). Note that at \( r = 0 \) the exact probability wavefunction is larger than that of the unperturbed probability wavefunction.
FIG. 5: Strong coupling regime: the parameters are $E_c = 0.1316$ eV, $E_m = 0.0395$ eV, $V = 0.26$ eV, $V/E_c = 1.98$ and $R/\ell = 0.3$. (a) Solid line is for $N = 0$ and $E = 0.017$ eV. Dashed line is for $N = 1$ and $E = 0.061$ eV. Inset: B-component of $|\Psi_0^{-1/2}(r)|^2$ and A- (dashed) and B- (solid) components of $|\Psi_T^{-1/2}(r)|^2$ in the absence of potential. (b) Solid line is for $N = 2$ and $E = 0.083$ eV. Dashed line is for $N = 3$ and $E = 0.101$ eV. Inset: A- and B-components of $|\Psi_2^{-1/2}(r)|^2$ and $|\Psi_3^{-1/2}(r)|^2$ in the absence of potential.

III. SCALING FUNCTION OF ELECTRON DENSITY

We have performed an extensive numerical evaluation of the electron density. The dimensionless induced density for $N = 0$ filled LL, $\ell^2 \Delta n_0(r/R)$, is plotted in Fig. 7 for various values of $(R/\ell, V/E_c)$. For $R/\ell < 1$ the induced density inside the barrier is positive, which is in sharp contrast to what usually happens in a barrier. The formation of bound states inside the barrier, as discussed in Sec. II B, is responsible for this effect. Note the induced density oscillates as a function of $r/R$. We have tested that the total integrated density is equal to the total number of electrons in the LL. The induced density satisfies the following two-parameter scaling function

$$\ell^2 \Delta n_0(r/R) = s_0(r/R, \frac{V}{E_c}, \frac{R}{\ell}).$$

As $R/\ell$ increases the sign of $\Delta n_0(0)$ changes sign from plus to minus, which is shown in Fig. 7. Physically this means positive induced density changes to negative induced density. For $\frac{V}{E_c} < 0.7$ our numerical results display data collapse, and is consistent with the following power law

$$\ell^2 \Delta n_0(0) \approx \left(\frac{V}{E_c}\right)^2 g_0(R/\ell).$$

As $R/\ell$ increases the sign of $\Delta n_0(0)$ changes sign from plus to minus, which is shown in Fig. 7. Physically this means positive induced density changes to negative induced density. For $\frac{V}{E_c} < 0.7$ our numerical results display data collapse, and is consistent with the following power law

FIG. 6: (a) Weak coupling regime: $|\Psi_0^{-1/2}(r)|^2$ for $R/\ell = 2.0$, $V/E_c = 2.172$, $R = 11$ nm, $V = 0.13$ eV, and $E = 0.11$ eV. A (B) component is solid (dashed) line. Inset: dashed line is without potential and solid is with potential. (b) Intermediate coupling regime: $|\Psi_0^{-1/2}(r)|^2$ for $R/\ell = 0.6$, $V/E_c = 0.607$, $R = 5$ nm, $V = 0.08$ eV, and $E = 0.013$ eV.

satisfies the following two-parameter scaling function

As $R/\ell$ increases the sign of $\Delta n_0(0)$ changes sign from plus to minus, which is shown in Fig. 7. Physically this means positive induced density changes to negative induced density. For $\frac{V}{E_c} < 0.7$ our numerical results display data collapse, and is consistent with the following power law

$$\ell^2 \Delta n_0(0) \approx \left(\frac{V}{E_c}\right)^2 g_0(R/\ell).$$

As $R/\ell$ increases the sign of $\Delta n_0(0)$ changes sign from plus to minus, which is shown in Fig. 7. Physically this means positive induced density changes to negative induced density. For $\frac{V}{E_c} < 0.7$ our numerical results display data collapse, and is consistent with the following power law

$$\ell^2 \Delta n_0(0) \approx \left(\frac{V}{E_c}\right)^2 g_0(R/\ell).$$

See Fig. 2. For a larger range of $\frac{V}{E_c} < 2.5$ an approximate data collapse can be obtained, see Fig. 8. The second order perturbative calculation in $V(r)$ agrees with scaling result when $R/\ell > 2.5$, but disagrees when $R/\ell < 2$, as shown in Fig. 2. It is noteworthy that $g_0(R/\ell)$ takes the minimum value near $R/\ell \approx 1.5$. This implies that the electron density is depleted most
FIG. 7: (a) $\ell^2 n(r)$ for $N = 0$ and $R/\ell \leq 1$. $\left(\frac{R}{\ell}, \frac{V}{E_c}\right) = (1.2, 1.215)$ (solid), $\left(\frac{R}{\ell}, \frac{V}{E_c}\right) = (0.6, 0.607)$ (dashed), $\left(\frac{R}{\ell}, \frac{V}{E_c}\right) = (0.3, 0.334)$ (dot). Dashed-dot line is $\ell^2 n(r)$ in the absence of the potential. (b) For $N = 0$ and $R/\ell > 1$. $\left(\frac{R}{\ell}, \frac{V}{E_c}\right) = (1.7, 2.582)$ (solid), $\left(\frac{R}{\ell}, \frac{V}{E_c}\right) = (1.5, 1.823)$ (dashed), $\left(\frac{R}{\ell}, \frac{V}{E_c}\right) = (1.2, 1.063)$ (dot).

FIG. 8: Approximate data collapse of $g_0(R/\ell)$ is obtained for a larger range of $V/E_c$ than the one used in Fig. 2. Values of $\left(\frac{V}{E_c}, R/\ell\right)$ used are shown in inset.

FIG. 9: $N = 0$ LL states must not overlap with $N = \pm 1$ LLs. Induced density at $r = 0$ is positive for $R/\ell < 1$.

FIG. 10: $\ell^2 n(r)$ for $N = 1$. $\left(\frac{R}{\ell}, \frac{V}{E_c}\right) = (1.5, 3.038)$ (dashed), $\left(\frac{R}{\ell}, \frac{V}{E_c}\right) = (0.6, 0.607)$ (dot), $\left(\frac{R}{\ell}, \frac{V}{E_c}\right) = (0.01, 0.607)$ (dashed dot). Solid line is $\ell^2 n(r)$ in the absence of the potential.

The induced density for $N = 1$ filled LL shown in Fig. 10 satisfies a similar scaling relation as that of $N = 0$ LL

$$\ell^2 \Delta n_1(r/R) = s_1(r/R, \frac{V}{E_c}, R/\ell). \quad (20)$$

At the origin $r = 0$ we find, for $\frac{V}{E_c} \ll 1$, the following scaling result

$$\ell^2 \Delta n_1(0) \approx \left(\frac{V}{E_c}\right)^{\delta_1} g_1(R/\ell), \quad (21)$$

strongly for $R/\ell \approx 1.5$. However, further decrease in $R/\ell$ has the opposite effect of increasing more penetration of electrons into the barrier. Near $R/\ell = 1$ the scaling function $g_0(R/\ell)$ changes sign. For $R/\ell < 1$ electrons accumulate in the barrier and the density becomes greater than the density of the unperturbed LL. This dependence on $R/\ell$ is thus strongly non-linear. For larger values of $V/E_c$ the boundary between positive and negative induced densities is displayed in Fig. 9.
where $\delta_1 = 1$. This result is obtained in the range $V/E_c < 0.1$ by data collapsing numerical data points, see Fig.11. The dependence of the induced density on $R/\ell$ is again strongly non-linear: $g_1(R/\ell)$ takes the minimum value near $R/\ell = 0.7$. For larger values of $R/\ell$ the boundary between positive and negative induced densities is displayed in Fig.12. As $V/E_c$ increases the range of $R/\ell$ where the induced density is positive expands. Note that for small values of $R/\ell$, for example 0.01, the value of $\ell$ at $B=1T$ is 257Å and R becomes comparable to the lattice constant so that Dirac equations breakdown. In this case smaller values of B must be used so that R can take larger values.

It can shown from perturbative analysis that, for chiral fermions, the first order correction of $V(r)$ absent, but the second order correction is present and is negative. The absence of the linear terms in $\frac{V}{E_c}$ the boundary between positive and negative induced densities is displayed in Fig.12. As $\frac{V}{E_c}$ increases the range of $R/\ell$ where the induced density is positive expands. Note that for small values of $R/\ell$, for example 0.01, the value of $\ell$ at $B=1T$ is 257Å and R becomes comparable to the lattice constant so that Dirac equations breakdown. In this case smaller values of B must be used so that R can take larger values.

It can shown from perturbative analysis that, for chiral fermions, the first order correction of $V(r)$ absent, but the second order correction is present and is negative. The absence of the linear terms in $\frac{V}{E_c}$ the boundary between positive and negative induced densities is displayed in Fig.12. As $\frac{V}{E_c}$ increases the range of $R/\ell$ where the induced density is positive expands. Note that for small values of $R/\ell$, for example 0.01, the value of $\ell$ at $B=1T$ is 257Å and R becomes comparable to the lattice constant so that Dirac equations breakdown. In this case smaller values of B must be used so that R can take larger values.

We now mention some general properties of the induced density of LLs. It has a critical point $y_{c,1}$, where

\[
\frac{\partial s_N(0,x,y)}{\partial y} = 0 \quad (x = \frac{V}{E_c} \text{ and } y = \frac{\delta}{\ell}).
\]

We find that $y_{c,1} \sim 1$. The scaling function takes the global minimum at $y_{c,1}$: as $y$ decreases the induced density becomes most negative at $y = y_{c,1}$, which suggests that it becomes increasingly more negative as $y$ increases. Below this critical point perturbative methods are inapplicable, and it separates strong and weak coupling regimes. The sign of the induced density changes at the second critical point $y_{c,2}$, where

\[
s_N(0,x,y)|_{y=y_{c,2}} = 0. \quad (23)
\]

As $y$ decreases below $y = y_{c,1}$ the induced density changes sign at $y = y_{c,2}$ and begins to take positive values.

**IV. SUMMARY AND DISCUSSIONS**

We find that a repulsive potential of graphene has bound states that are peaked inside the barrier with tails extending over $\ell(N + 1)$. The properties of these bound-states change as $R/\ell$ varies, and affect the induced density of filled LLs inside the barrier in a non-trivial way as a function of $R/\ell$. As $R/\ell$ decreases the induced density inside the barrier becomes more negative, but as it reaches a critical value the induced density reaches an extremum value. Upon further decrease of $R/\ell$ the value of the induced density reaches zero, and, after this, it becomes positive. These changes are strongly non-linear in $R/\ell$, and one moves successively from weak, intermediate, and strong coupling regimes as $R/\ell$ decreases. The condition $V/E_c \ll 1$ is not sufficient for treating $V(r)$ perturbatively, and, in addition to this, one must require $R/\ell \gg 1$ for both chiral and non-chiral fermions.

For filled LLs electron-electron interactions may be approximated well by a Hartree-Fock (HF) method\[20]. The electron density in HF method is given by the sum of unrenormalized single electron probability wavefunctions, just as in Eq.2. So our calculation of the induced density is actually a HF result. However, our single electron energies are not the renormalized HF result. This will somewhat affect our numerical estimate of the boundary between overlapping LLs of Figs.9 and 12. The discontinuity in the potential of Eq.8 can couple states in K and K’ valleys, which is ignored in our approach.

**FIG. 11:** $g_1(R/\ell)$ is obtained by data collapse for $N = 1$ and $\frac{V}{E_c} \ll 1$. Values of $\frac{V}{E_c}, R/\ell$ used are shown in inset.

**FIG. 12:** $N = 1$ LL states must not overlap with $N = 0, 2$ LLs. The range of $R/\ell$, where the induced density at $r = 0$ is positive increases with increasing $V/E_c$. 
However, our tight-binding calculations show that this coupling is small [16].

There is a symmetry [16] between repulsive and attractive potentials $V(r)$ and $-V(r)$ so that the induced densities of these potentials are identical. In the presence of a repulsive or attractive potential, both charge accumulation and depletion occur, depending on the value of $R/\ell$, see Figs. 8 and 12. The appearance of a charge accumulation near a repulsive potential, for example, could be explained by introducing an attractive potential via the transformation $V(r) \rightarrow -V(r)$, but this same transformation would fail to explain charge depletion since electrons would pile up around the transformed attractive potential. Thus charge depletion and accumulation cannot be explained simultaneously in either perspective of repulsive or attractive potential. In addition, the critical points $R/\ell = y_{c,1}$ and $y_{c,2}$, where the scaling function takes the global minimum and where it changes sign cannot be explained by application $V(r) \rightarrow -V(r)$. It would be desirable to construct an analytic theory for them.

Properties of the bound states of the potential barrier may be observed as follows. A localized potential may be created by a circular gate placed on graphene sheet. When this gate is sufficiently close to the edge of the sample coupling between bound states and edge states may be induced, and the transmission coefficients of edge states may reveal properties of the bound states. Also these bound states may play an important role in transport and magnetic properties of graphene [26].

S.R.E.Y. thanks Philip Kim for valuable discussions on various aspects of this paper. This work was supported by the Korea Research Foundation Grant funded by the Korean Government (KRF-2009-0074470).

[20] It should be noted that a localized potential couples chiral LL states to non-chiral LL states, and thus makes the $N = 0$ band states slightly non-chiral. Since these states are dominantly chiral we will call them chiral states. In $N = 1$ states both A and B components are present, and these states are non-chiral.
