Tenosynovial giant cell tumor
Cruciate ligament

ABSTRACT

Introduction: Tenosynovial giant cell tumor (TSGCT) is a slow-growing soft tissue tumor that develops from the synovial tissue of tendon sheaths, joints, or bursae. In the knee, this type of tumor is uncommon. Giant cell tumors of the cruciate ligaments' tendon sheath are far more infrequent. Only 16 localized TSGCTs of the cruciate ligaments have been recorded in the literature to our knowledge, with 9 involving the anterior cruciate ligament (ACL) and 7 involving the posterior cruciate ligament (PCL).

Case presentation: We present a rare case of localized TSGCT arising from the PCL's femoral insertion in a 44-year-old male, as well as a literature review on localized TSGCT of cruciate ligaments in the knee. The diagnosis of tumor's presence was made using MRI while the definitive diagnosis was obtained through intraoperative evaluation and postoperative pathology.

Conclusion: Arthroscopic tumor resection was an effective and safe treatment option based on the available data.

1. Introduction

TSGCT is a soft tissue tumor that develops locally in the synovial tissue of tendon sheaths, joints, or bursae. This type of tumor is quite uncommon in the knee [1]. TSGCT that develops locally from the cruciate ligament is much more uncommon. Only 16 cases of localized TSGCT of the cruciate ligament have been reported in the English literature, including 9 cases of the ACL [2–8] and 7 cases of the PCL [6,9–14]. Otsuka [3] described the first case of TSGCT originating from ACL. Sheppard [10] described the first case of TSGCT arising from PCL. Due to the rarity of this condition, there are no guidelines for diagnosis, treatment, or postoperative follow-up and evaluation. We describe a case of TSGCT of the PCL that we initially mistook for a Cyclops lesion. This case report has been reported in line with the SCARE Criteria [15].

2. Case presentation

A 44-year-old male patient complained of discomfort in the left knee while extending for two months. The pain began spontaneously and was vague. The patient previously underwent conservative treatment for a grade II PCL injury ten years ago. Clinical examination revealed that the range of motion of the knee was normal. Prior to the onset of the pain, the patient was able to participate in amateur basketball without incident. The patient's MRI revealed a 1.8 × 1.2 × 1.0 cm mass in the intercondylar area, located anterior to the ACL but originating from the PCL's femoral insertion. Additionally, the MRI showed an earlier PCL injury with a synovial cyst behind it (Fig. 1).

At first, we believed that the mass was fibrous tissue caused by PCL injury. However, endoscopic examination revealed a yellowish, pinkish, and partially gleaming white tumor that was continuous with the synovial membrane at the PCL's femoral origin. The tumor became trapped between the ACL and the intercondylar notch during extension (Fig. 2). The PCL was stretched, impairing its function. By extending the anteromedial portal, we were able to detach the tumor from the PCL and entirely remove it by using a radiofrequency device. The tumor was measured to be 1.8 × 1.2 × 1.0 cm in size, which was consistent with the size measured on MRI (Fig. 3). The superficial synovial membrane of the PCL was completely removed along with the tumor, leaving only the...
normal fibrous structure. We made no more interventions. The histopathology findings verified the characteristic lesions of TSCTG (Fig. 4). Following surgery, the patient was promptly admitted to rehabilitation and did not receive radiation therapy. After three months, the range of motion of the knee was fully normal, and the patient’s pain disappeared.

3. Discussion

TSGCTs are benign, slow-growing tumors that account for approximately 1.6% of soft tissue tumors. They are most frequently seen in the hands (76% of cases), followed by the feet (12%). Only 4% of cases occur in the knee. TSGCTs occur from 4 to 80 years old but are most prevalent between the ages of 30 and 40, with a female/male ratio of around 2:1 [1]. TSGCT of the cruciate ligaments are exceedingly unusual while they have been documented in only a few cases. Gülenç et al. [5] reported the largest series of intra-articular TSGCT of the knee, with seven patients, of which 3 cases originated from the anterior cruciate ligament. Flevas et al. [6] described two cases, one with ACL and one with PCL. Besides the cruciate ligaments, intra-articular TSGCT of the knee can also originate from the fat pad [16,17], the medial plicae [18], the anterior horn of the medial meniscus [19], the lateral retinaculum, the patellar tendon [5], and the ligamentum membrane [20]. We only found 16 cases of TSGCT of the cruciate ligaments reported in literature, comprising 9 cases of ACL and 7 cases of PCL. The average age of these 16 cases was 32 years (18–54), with 7 women and 9 men involved. Four of the thirteen cases with information happened in the left knee, while nine occurred in the right knee.

TSGCTs of the hand or foot are often asymptomatic [1]. However, the most typical clinical presentations of TSGCT of the cruciate ligaments are pain and decreased range of motion of the knee, frequently without an obvious history of trauma. In 16 TSGCTs of the cruciate ligament, except for three cases in Gülenç’s report [5] for which data were not available, all remaining patients experienced pain, with 50% having limited range of motion (Table 1). The average time between symptom onset and operation was 2 years (0–5 years). Over 60% of cases were found six months after initiation. Only two cases in Flevas’
report [6] were diagnosed immediately after the beginning of symptoms. Only 1/16 of reported cases had a two-month prior history of trauma, and that injury also triggered the pain [10]. Clinical evaluation of all reported cases revealed no evidence of ligament or meniscus injury. In our case, the patient experiences a popping sound when gradually extending the knee from 20 to 30 degrees to full extension, in addition to the pain. We decided to perform endoscopic excision of the lesion without reconstruction of the PCL because the patient was still physically active and had not complained of any other issues before the onset.

According to the literature, MRI is the primary approach for confirming the diagnosis of a tumor in the knee joint. TSGCT of the cruciate ligaments could only be definitively diagnosed based on intraoperative evaluation and postoperative pathology. Except for three cases for which data were unavailable, all the remaining cases were undetected on knee X-rays and regular laboratory tests (Table 1). In all cases, the MRI revealed visible masses. Due to the rarity of TSGCT of the cruciate ligament, its characteristics on MRI have not been well studied, and the MRI is only effective for confirming the presence of a tumor, but not for determining the exact original location or type of tumor. There were 4 of 16 patients who had preoperative diagnostic biopsies. The remaining authors established a clear diagnosis based on their examination of the tumor’s origin during surgery and postoperative pathology. The tumor’s size varies from 1 to 5 cm [12,13]. The size of our patient’s tumor was 1.8 × 1.2 × 1 cm.

Arthroscopic tumor removal is the favorite treatment option for TSGCTs located in the cruciate ligament. According to previous reports, 13/16 patients had endoscopic tumor removal, while only three cases underwent open surgery, including two cases of PCL adjacent to the posterior capsule [10,11] and one case of ACL. Most of the tumors were located in the fat pad [2]. Although no additional adjuvant treatment such as radiation therapy was given following surgery, the authors observed no recurrence in either open or endoscopic surgery cases. Although the total recurrence rate of TSGCTs varied between 7 and 29%
[21], no recurrence was seen at follow-up ranging from 6 months to 4.5 years in 16 reported cases (Table 1). Our patient has only been observed for three months after surgery, however, we believe, like Xu et al. [9], that there will be no recurrence once the tumor has been entirely excised by endoscopy. Our patient will be re-examined with MRI every six months for the first two years. In case of relapse, reintervention by endoscopic surgery could be considered.

4. Conclusion

Localized TSGCT of the cruciate ligaments of the knee are extremely uncommon and have received insufficient attention. The primary signs are pain and limited range of motion. The diagnosis of the tumor's presence is made using MRI while a definitive diagnosis is obtained through intraoperative evaluation and postoperative pathology. Based on the available data, arthroscopic tumor resection is an effective and safe treatment option.

Consent

Written informed consent was obtained from the patient for publication of this case report and accompanying images. A copy of the written consent is available for review by the Editor-in-Chief of this journal on request.

Provenance and peer review

Not commissioned, externally peer-reviewed.

Ethical approval

The procedures used in this study inhere to the tenets of the Declarations of Helsinki.

Funding

We declare no funding for this study.

Guarantor

Professor Dung Tran Trung MD, PhD.

Research registration number

This is a case report, so I do not have to register.
