THE BEAM-GAS METHOD FOR LUMINOSITY MEASUREMENT AT LHCb

P. HOPCHEV

France

The high resolution of the LHCb vertex detector makes it possible to perform precise measurements of the vertex positions of beam-gas and beam-beam interactions. With these measurements beam parameters such as width and position can be measured. A novel method for determining the absolute luminosity at the LHC using the directly measured beam parameters is presented. The data taken in 2009 is used to illustrate the procedure.

1 Plans for luminosity measurement in LHCb

Luminosity is a fundamental accelerator characteristic, related to the amount of collisions produced. The rate of a certain process can be expressed as the product of the the cross-section for that process and the instantaneous luminosity. LHCb is a forward spectrometer at the LHC optimised for precise studies of heavy flavour decays\cite{1}. In addition, the unique pseudo-rapidity coverage (2 < y < 5) of the detector will allow interesting measurements of production cross-sections in a hitherto unexplored kinematic region. For these measurements, good knowledge of the luminosity is essential. In LHCb several methods for measuring the luminosity are under investigation.

1. Beam imaging with gas\cite{2}, which is described in this paper
2. van der Meer scan, which consists of moving the two beams against each other, while measuring the interaction rate
3. Several indirect methods using processes with well known cross-sections, e.g. Z-boson and elastic diphoton dimuon production

2 Beam-gas luminosity method

In a circular collider the luminosity for 2 colliding bunches of particles can be expressed in the following way\cite{3}:

\[
L = f N_1 N_2 2c \cos^2(\phi/2) \int \rho_1(x,t) \rho_2(x,t) \, d^3x \, dt
\]

where \( f \) is the revolution frequency of the two counter-rotating bunches travelling with the speed of light \( c \), \( N_{1,2} \) are the bunch intensities, \( \phi \) is the beams crossing angle and \( \rho_{1,2} \) are the time- and space-dependent bunch densities. The integral in Eq. 1 is known as the beam overlap integral.
The beam-gas luminosity method is based on the detection of beam-gas vertices. The position of the beam-gas interactions can be used to measure the beam angles, profiles and relative positions. At a first approximation we can neglect possible phase shifts and do not consider effects from the longitudinal shape of the bunches. Then, having the transverse shapes of the bunches, we can calculate the overlap integral. The second important ingredient are the bunch intensities, knowledge of which comes from instrumentation installed and operated by the accelerator team.

Once the absolute luminosity is measured with satisfactory precision we will calibrate a reference cross-section and dedicated “lumi counters” in order to propagate the knowledge of the absolute scale. Currently the beam-gas luminosity method is being applied for a first time.

3 VELO vertex reconstruction

The LHCb vertex detector, the VELO, is located around the LHC interaction point 8 and can be used to reconstruct interaction vertices arising from beam-beam collisions and collisions between the beam protons and atoms of the residual gas in the beam-pipe. The VELO consists of 21 stations of radial and azimuthal silicon-strip sensors, see Fig. 1. In addition two backward stations, the so called ‘pile-up’ system, are used for providing a signal at the earliest level of the trigger system.

Figure 1: A simplified sketch of the VELO, including the 2 pile-up stations on the left. The colour arrows indicate the direction of the two LHC beams and example trajectories of the collision products from beam-gas interactions. Only the products of the beam1-gas interactions fly into the acceptance of the LHCb spectrometer.

In November 2009 LHC delivered its first proton-proton collisions at center of mass energy equal to 900GeV. In the following weeks several million collision events were recorded by LHCb. The events were triggered by activity in the calorimeter system or from significant activity in the pile-up system in the backward region of the VELO.

The vertex resolution for beam-beam interactions has been estimated with the data collected in 2009. Preliminary results are shown in Fig. 2. In 2009 the VELO was not fully closed and each of the two halves was retracted by 15 mm in the horizontal direction (along the x-axis). This leads to a worse resolution in x. For beam-gas interactions outside the luminous region we also take into account the dependence of the vertex resolution on the position of the vertex along the beam direction.

4 Measured beam properties

The VELO is positioned very close to the beam-axis which determines its very good acceptance for beam-gas events along a wide range in z, where z is the coordinate measured parallel to the beam axis, see Fig. 3(a). The x-z and y-z projections of the positions of the reconstructed beam-gas vertices can be used to determine the beams slopes and widths. Fig. 3(b) shows the measured beam slopes during one of the 2009 runs.
Figure 2: Preliminary estimate of the VELO vertex resolution in the 2009 runs. The resolution in the transverse directions (x and y) for beam-beam interactions are shown as function of the number of tracks per reconstructed vertex.

Figure 3: Positions of reconstructed beam-gas vertices. (a) Distributions of the z-position of the reconstructed beam-gas (blue and red) and beam-beam (black) vertices. The asymmetry in the number of reconstructed beam1-gas and beam2-gas interactions is due to the different trigger efficiency. (b) Positions in the horizontal (x-z) and vertical (y-z) planes of the reconstructed vertices from beam-gas interactions. The observed crossing angle in the x-z plane is due to the LHCb dipole magnet and is in agreement with the expected value.

The measured beam and luminous-region sizes in the y-direction are shown in Fig. 4. One of the two colliding bunch pairs has been used to demonstrate the measurement. The overlap of the two beams in the interaction point is important for optimizing the luminosity. Using the beams directions and sizes one can also make a prediction about the collision region and learn more about the systematic effects which have impact on its position and shape, Fig. 5.

5 Summary and prospects

The presented preliminary studies show the feasibility of the beam-gas luminosity method. For 2009 data the expected precision on the absolute luminosity is about 20%, decomposed roughly into 10% from the measurement of the beam overlap and 15% from the measurement of the beam intensities. It has been shown that the vertex resolution plays a small, but not

*The final analysis of the 2009 luminosity using this method in fact achieved a relative precision of 15%.*
negligible role in the determination the sizes of the beams. In 2010 more extensive studies will be possible allowing better estimate of the systematics and the higher amount of data will result in a decreased uncertainty. Considerable effort has been put into providing more precise beam intensity measurements. Therefore for 2010 we expect very competitive results on the precision of the determined luminosity.
