Abstract

We make progress on two important problems regarding attribute efficient learnability.

First, we give an algorithm for learning decision lists of length $k$ over $n$ variables using $2^{O(k^{1/3})} \log n$ examples and time $n^{O(k^{1/3})}$. This is the first algorithm for learning decision lists that has both subexponential sample complexity and subexponential running time in the relevant parameters. Our approach establishes a relationship between attribute efficient learning and polynomial threshold functions and is based on a new construction of low degree, low weight polynomial threshold functions for decision lists. For a wide range of parameters our construction matches a 1994 lower bound due to Beigel for the ODDMAXBIT predicate and gives an essentially optimal tradeoff between polynomial threshold function degree and weight.

Second, we give an algorithm for learning an unknown parity function on $k$ out of $n$ variables using $O(n^{1-1/k})$ examples in time polynomial in $n$. For $k = o(\log n)$ this yields a polynomial time algorithm with sample complexity $o(n)$. This is the first polynomial time algorithm for learning parity on a superconstant number of variables with sublinear sample complexity.

1 Introduction

1.1 Attribute Efficient Learning

A central goal in machine learning is to design efficient, effective algorithms for learning from small amounts of data. An obstacle to achieving this goal is that learning problems are often characterized by an abundance of irrelevant information. In many learning problems each data point is naturally viewed as a high dimensional vector of attribute values; as a motivating example, in a natural language domain a data point representing a text document may be a vector of word frequencies over a lexicon of 100,000 words (attributes). A newly encountered word in a corpus may typically have a simple definition which uses only a dozen or so words from the entire lexicon. One would like to be able to learn the meaning of such a word using a number of examples which is closer to a dozen (the actual number of relevant attributes) than to 100,000 (the total number of attributes).

Towards this end, an important goal in machine learning theory is to design attribute efficient algorithms for learning various classes of Boolean functions. A class $C$ of Boolean functions over $n$ variables $x_1, \ldots, x_n$ is said to be attribute-efficiently learnable if there is a poly($n$) time algorithm which can learn any function $f \in C$ using a number of examples which is polynomial in the “size” (description length) of the function $f$ to be learned, rather than in $n$ (the number of features in the domain over which learning takes place). (Note that the running time of the learning algorithm must in general be at least $n$ since each example is an $n$-bit vector.) Thus an attribute efficient learning algorithm for, say, the class of Boolean conjunctions must be able to learn any Boolean conjunction of $k$ literals over $x_1, \ldots, x_n$ using poly($k, \log n$) examples, since $k \log n$ bits are required to specify such a conjunction.

1.2 Decision Lists

A longstanding open problem in machine learning, posed first by Blum in 1990 [4, 8, 10] and again by Valiant in 1998 [35], is to determine whether or not there exist attribute efficient algorithms for learning decision lists. A decision list is essentially a nested “if-then-else” statement (we give a precise definition in Section 2).

Attribute efficient learning of decision lists is of both theoretical and practical interest. Blum’s motivation for considering the problem came from the infinite attribute model [4]; in this model there are infinitely many attributes but the concept to be learned depends on only a small number of them, and each example consists of a finite list of active attributes. Blum et al. [8] showed that for a wide range of concept classes (including decision lists) attribute efficient learnability in the standard $n$-attribute model is equivalent to learnability in the infinite attribute model. Since simple classes such as disjunctions and conjunctions are attribute efficiently learnable (and hence learnable in the infinite attribute model), this motivated Blum [4] to ask whether the richer class of decision lists is thus learnable as well.¹ Several researchers have subsequently considered this problem, see e.g. [6, 10, 12, 29, 32]; we summarize some of this previous work in Section 1.6.

From an applied perspective, Valiant [35] relates the problem of learning decision lists attribute efficiently to the question “how can human beings learn from small amounts of data in the presence of irrelevant information?” He points out that since decision lists play an important role in various models of cognition, a first step in understanding this phenomenon would be to identify efficient algorithms which learn decision lists from few examples. Due to the lack of progress in developing such algorithms for decision lists, Valiant suggests that models of cognition should perhaps focus on “flatter” classes of functions such as projective DNF [35].

¹Additional motivation comes from the fact that decision lists have such a simple algorithm in the PAC model.
1.3 Parity Functions

Another outstanding challenge in machine learning is to determine whether there exist attribute efficient algorithms for learning parity functions. The parity function on a set of 0/1-valued variables \(x_1, \ldots, x_k\) is equal to \(x_1 + \cdots + x_k \mod 2\). As with the class of decision lists, a simple PAC learning algorithm is known for the class of parity functions but no attribute efficient PAC learning algorithm is known. Learning parity functions plays an important role in Fourier learning methods [27] and is closely related to decoding random linear codes [9]. Both A. Blum [6] and Y. Mansour [25] cite attribute efficient learning of parity functions as an important open problem.

1.4 Our Results: Decision Lists

We give the first learning algorithm for decision lists that is subexponential in both sample complexity (in the relevant parameters \(k\) and \(\log n\)) and running time (in the relevant parameter \(k\)).

Our results demonstrate for the first time that it is possible to simultaneously avoid the “worst case” in both sample complexity and running time, and thus suggest that it may indeed be possible to learn decision lists attribute efficiently.

Our main learning result for decision lists is:

Theorem 1 There is an algorithm for learning decision lists over \(\{0, 1\}^n\) which, when learning a decision list of length \(k\), has mistake bound \(2^{\tilde{O}(k^{1/3})}\log n\) and runs in time \(n^{\tilde{O}(k^{1/3})}\).

We prove Theorem 1 in two parts; first we generalize Littlestone’s well known Winnow algorithm [22] for learning linear threshold functions to learn polynomial threshold functions. In previous learning results, polynomial threshold functions are learned by applying techniques from linear programming: a Boolean function computed by a polynomial threshold function of degree \(d\) can be learned in time \(n^{O(d)}\) by using polynomial time linear programming algorithms such as the Ellipsoid algorithm (see e.g. [20]). In contrast, we use the Winnow algorithm to learn polynomial threshold functions. Winnow learns using few examples in a small amount of time provided that the degree of the polynomial is low and the integer coefficients of the polynomial are not too large:

Theorem 2 Let \(C\) be a class of Boolean functions over \(\{0, 1\}^n\) with the property that each \(f \in C\) has a polynomial threshold function of degree at most \(d\) and weight at most \(W\). Then there is an online learning algorithm for \(C\) which runs in \(n^d\) time per example and has mistake bound \(O(W^2 \cdot d \cdot \log n)\).

At this point we have reduced the problem of learning decision lists attribute efficiently to the problem of representing decision lists with polynomial threshold functions of low weight and low degree. To this end we prove

Theorem 3 Let \(L\) be a decision list of length \(k\). Then \(L\) is computed by a polynomial threshold function of degree \(\tilde{O}(k^{1/3})\) and weight \(2^{\tilde{O}(k^{1/3})}\).

Theorem 1 follows directly from Theorems 2 and 3.

Polynomial threshold function constructions have recently been used to obtain the fastest known algorithms for a range of important learning problems such as learning DNF formulas [20], intersections of halfspaces [19], and Boolean formulas of superconstant depth [30]. For each of these learning problems the sole goal was to obtain fast learning algorithms, and hence the only parameter

\[2\] Throughout this section we use “sample complexity” and “mistake bound” interchangeably; as described in Section 2 these notions are essentially identical.
of interest in these polynomial threshold function constructions is their degree, since degree bounds translate directly into running time bounds for learning algorithms (see e.g. [20]). In contrast, for the decision list problem we are interested in both the running time and the number of examples required for learning. Thus we must bound both the degree and the weight (magnitude of integer coefficients) of the polynomial threshold functions which we use.

Our polynomial threshold function construction is essentially optimal in the tradeoff between degree and weight which it achieves. In 1994 Beigel gave a lower bound showing that any degree $d$ polynomial threshold function for a particular decision list must have weight $2^\Omega(n/d^2)$. For $d = n^{1/3}$, Beigel’s lower bound implies that the construction stated in Theorem 3 is essentially optimal. Furthermore, for any decision list $L$ of length $n$ and any $d \leq n^{1/3}$, we will in fact construct polynomial threshold functions of degree $d$ and weight $2^{O(n/d^2)}$ computing $L$. Beigel’s lower bound thus implies that our degree $d$ polynomial threshold functions are of roughly optimal weight for all $d \leq n^{1/3}$, and hence strongly suggests that our analysis is the best possible for the algorithm we use.

1.5 Our Results: Parity Functions

For parity functions, we give an $O(n^3)$ time algorithm which can learn an unknown parity on $k$ variables out of $n$ using $O(n^{1-1/k})$ examples. For values of $k = o(\log n)$ the sample complexity of this algorithm is $o(n)$. This is the first algorithm for learning parity on a superconstant number of variables with sublinear sample complexity.

The standard PAC learning algorithm for learning an unknown parity function is based on viewing a set of $m$ labelled examples as a system of $m$ linear equations modulo 2. Using Gaussian elimination it is possible to solve the system and find a consistent parity function. It can be shown that the solution thus obtained is a “good” hypothesis if its weight (number of nonzero entries) is small relative to $m$, the number of examples. However, using Gaussian elimination can result in a solution of weight as large as $\min(m, n)$ even if $k$ (the number of variables in the target parity) is very small. Thus in order for this approach to give a successful learning algorithm, it is necessary to use $m = \Omega(n)$ examples regardless of the value of $k$. In contrast, observe that an attribute efficient algorithm for learning a parity of length $k$ should use only $\text{poly}(k, \log n)$ examples.

Our algorithm works by finding a “low weight” solution to a system of $m$ linear equations. We prove that with high probability we can find a solution of weight $O(n^{1-1/k})$ irrespective of $m$. Thus by taking $m$ to be only slightly larger than $n^{1-1/k}$ we have that our solution is a “good” hypothesis.

1.6 Previous Results: Decision Lists

In previous work several algorithms with different performance bounds (in terms of running time and number of examples used) have been given for learning decision lists.

- Rivest [31] gave the first algorithm for learning decision lists in Valiant’s PAC model of learning from random examples. Littlestone [6] subsequently gave an analogue of Rivest’s algorithm in the online learning model. The algorithm can learn any decision list of length $k$ in $O(kn^2)$ time using $O(kn)$ examples.

- A brute-force approach to learning decision lists of length $k$ is to maintain a collection of all such lists which are consistent with the examples seen so far, and to predict at each stage using majority vote over the surviving hypotheses. This “halving algorithm” (proposed in various forms by Barzdin and Freivald [2], Mitchell [26], and Angluin [1]) can learn decision lists of length $k$ using only $O(k \log n)$ examples, but the running time is $n^{O(k)}$. 
• Several researchers [6, 35] have observed that Littlestone’s well-known Winnow algorithm [22] can learn decision lists of length \( k \) from \( 2^{O(k)} \log n \) examples in time \( 2^{O(k)} n \log n \). This follows from the observation that decision lists of length \( k \) can be viewed as linear threshold functions with integer coefficients of magnitude \( 2^{\Theta(k)} \). We note that our algorithm in this paper always has improved sample complexity over the basic Winnow algorithm, and for \( k \geq (\log n)^{3/2} \) our approach improves on the time complexity of Winnow as well.

• Finally, several researchers have considered the special case of learning a decision list of length \( k \) over \( n \) variables in which the output bits of the decision list have at most \( D \) alternations. Valiant [35] and Nevo and El-Yaniv [29] have given refined analyses of Winnow’s performance for this special case, and Dhagat and Hellerstein [12] have also studied this problem. However, for the general case in which \( D \) can be as large as \( k \), the results thus obtained do not improve on the straightforward Winnow analysis described in the previous bullet.

These previous algorithmic results are summarized in Figure 1. We observe that all of these earlier algorithms have an exponential dependence on the relevant parameter(s) (\( k \) and \( \log n \) for sample complexity, \( k \) for running time) for either the running time or the sample complexity.

| Reference:          | Number of examples: | Running time:       |
|---------------------|---------------------|---------------------|
| Rivest / Littlestone | \( O(kn) \)         | \( O(kn^2) \)       |
| Halving algorithm   | \( O(k \log n) \)   | \( n^{O(k)} \)      |
| Winnow algorithm    | \( 2^{O(k)} \log n \) | \( 2^{O(k)} n \log n \) |
| This Paper          | \( 2^{O(k^{1/3})} \) \( \log n \) | \( n^{O(k^{1/3})} \) |

Table 1: Comparison of known algorithms for learning decision lists of length \( k \) on \( n \) variables.

1.7 Previous Results: Parity Functions

Little previous work has been published on learning parity functions attribute efficiently in the PAC model. The standard PAC learning algorithm for parity (based on solving a system of linear equations) is due to Helmbold et al. [17]; however as described above this algorithm is not attribute efficient since it uses \( \Omega(n) \) examples.

Several authors have considered learning parity attribute efficiently in a model where the learner is allowed to make membership queries. Attribute efficient learning is easier in this framework since membership queries can help identify relevant variables. Blum et al. [8] give a randomized polynomial time membership-query algorithm for learning parity on \( k \) variables using only \( O(k \log n) \) examples. These results were later refined by Uehara et al. [34].

1.8 Organization

In Section 2 we give the necessary background on online learning and polynomial threshold functions. In Section 3 we show how known results from learning theory enable us to reduce the decision list learning problem to a problem of finding suitable polynomial threshold function representations of decision lists. In Sections 4.1 and 4.2 we give two different proofs of a weak tradeoff between degree and weight for polynomial threshold function representations of decision lists, and in Section 4.3 we combine these techniques to prove Theorem 3. In Section 5 we show how to apply our
techniques to give a tradeoff between sample complexity and running time for learning decision trees. In Section 6 we discuss the connection with Beigel’s ODDMAXBIT lower bound and related issues. In Section 7 we give our new algorithm for learning parity functions, and in Section 8 we suggest directions for future work.

2 Preliminaries

Attribute efficient learning has been chiefly studied in the on-line mistake-bound model of concept learning which was introduced in [22][23]. In this model learning proceeds in a series of trials, where in each trial the learner is given an unlabelled boolean example \(x \in \{0,1\}^n\) and must predict the value \(f(x)\) of the unknown target function \(f\). After each prediction the learner is given the true value of \(f(x)\) and can update its hypothesis before the next trial begins. The mistake bound of a learning algorithm on a target concept \(c\) is measured by the worst-case number of mistakes that the algorithm makes over all (possibly infinite) sequences of examples, and the mistake bound of a learning algorithm on a concept class (class of Boolean functions) \(C\) is the worst-case mistake bound across all functions \(f \in C\). The running time of a learning algorithm \(A\) for a concept class \(C\) is defined as the product of the mistake bound of \(A\) on \(C\) times the maximum running time required by \(A\) to evaluate its hypothesis and update its hypothesis in any trial.

Our main interests in this paper are the classes of decision lists and parity functions.

A decision list \(L\) of length \(k\) over the Boolean variables \(x_1, \ldots, x_n\) is represented by a list of \(k\) pairs and a bit

\[(\ell_1, b_1), (\ell_2, b_2), \ldots, (\ell_k, b_k), b_{k+1}\]

where each \(\ell_i\) is a literal and each \(b_i\) is either \(-1\) or \(1\). Given any \(x \in \{0,1\}^n\), the value of \(L(x)\) is \(b_i\) if \(i\) is the smallest index such that \(\ell_i\) is made true by \(x\); if no \(\ell_i\) is true then \(L(x) = b_{k+1}\).

A parity function of length \(k\) is defined by a set of variables \(S \subset \{x_1, \ldots, x_n\}\) such that \(|S| = k\). The parity function \(\chi_S(x)\) takes value 1 on inputs which set an even number of variables in \(S\) to 1 and takes value \(-1\) on inputs which set an odd number of variables in \(S\) to 1.

Given a concept class \(C\) over \(\{0,1\}^n\) and a Boolean function \(f \in C\), let \(\text{size}(f)\) denote the description length of \(f\) under some reasonable encoding scheme. (Note that if \(f\) has \(r\) relevant variables then \(\text{size}(f)\) will be at least \(r \log n\) since this many bits are required just to specify which variables are relevant.) We say that a learning algorithm \(A\) for \(C\) in the mistake-bound model is attribute-efficient if the mistake bound of \(A\) on any concept \(c \in C\) is polynomial in \(\text{size}(f)\). In particular, the description length of a length \(k\) decision list (parity) is \(O(k \log n)\), and thus we would ideally like to have an algorithm which learns decision lists (parities) of length \(k\) with a mistake bound of poly\((k, \log n)\) and runs in time poly\((n)\).

(We note here that attribute efficiency has also been studied in other learning models, namely Valiant’s Probably Approximately Correct (PAC) model of learning from random examples. Standard conversion techniques are known [1][16][23] which can be used to transform any mistake bound algorithm into a PAC learning algorithm. This transformation essentially preserves the running time of the mistake bound algorithm, and the sample size required by the PAC algorithm is essentially the mistake bound. Thus, positive results for mistake bound learning, such as those we give for decision lists in this paper, directly yield corresponding positive results for the PAC model.)

Finally, our results for decision lists are achieved by a careful analysis of polynomial threshold functions. Let \(f\) be a Boolean function \(f : \{0,1\}^n \rightarrow \{-1,1\}\) and let \(p\) be a polynomial in \(n\) variables with integer coefficients. Let \(d\) denote the degree of \(p\) and let \(W\) denote the sum of the absolute values of \(p\)'s integer coefficients. If the sign of \(p(x)\) equals \(f(x)\) for every \(x \in \{0,1\}^n\), then we say that \(p\) is a polynomial threshold function of degree \(d\) and weight \(W\) for \(f\).
3 Expanded-Winnow: Learning Polynomial Threshold Functions

Littlestone introduced the online Winnow algorithm in 1988 and showed that it can attribute efficiently learn Boolean conjunctions, disjunctions, and low weight linear threshold functions. Throughout its execution Winnow maintains a linear threshold function as its hypothesis; at the heart of the algorithm is a novel update rule which makes a multiplicative update to each coefficient of the hypothesis (rather than an additive update as in the Perceptron algorithm) each time a mistake is made. Since its introduction Winnow has been intensively studied from both applied and theoretical standpoints (see e.g. [7, 14, 18, 33]) and multiplicative updates have become widespread in machine learning algorithms.

The following theorem (which, as noted in [35], is implicit in Littlestone’s analysis in [22]) gives a mistake bound for Winnow when learning linear threshold functions:

Theorem 4 Let \( f(x) \) be the linear threshold function \( \text{sign}(\sum_{i=1}^{n} w_i x_i - \theta) \) where \( \theta \) and \( w_1, \ldots, w_n \) are integers. Let \( W = \sum_{i=1}^{n} |w_i| \). Then Winnow learns \( f(x) \) with mistake bound \( O(W^2 \log n) \), and uses \( n \) time steps per example.

We will use a generalization of the Winnow algorithm, called Expanded-Winnow, to learn polynomial threshold functions of degree at most \( d \). Our generalization introduces \( \sum_{i=1}^{d} \binom{n}{d} \) new variables (one for each monomial of degree up to \( d \)) and runs Winnow to learn a linear threshold function over these new variables. More precisely, in each trial we convert the \( n \)-bit received example \( x = (x_1, \ldots, x_n) \) into a \( \sum_{i=1}^{d} \binom{n}{d} \) bit expanded example (where the bits in the expanded example correspond to monomials over \( x_1, \ldots, x_n \)), and we give the expanded example to Winnow. Thus the hypothesis which Winnow maintains – a linear threshold function over the space of expanded features – is a polynomial threshold function of degree \( d \) over the original \( n \) variables \( x_1, \ldots, x_n \).

Theorem 2 which follows directly from Theorem 4 summarizes the performance of Expanded-Winnow:

Theorem 2 Let \( C \) be a class of Boolean functions over \( \{0, 1\}^n \) with the property that each \( f \in C \) has a polynomial threshold function of degree at most \( d \) and weight at most \( W \). Then Expanded-Winnow algorithm runs in \( n^d \) time per example and has mistake bound \( O(W^2 \cdot d \cdot \log n) \) for \( C \).

Theorem 2 shows that the degree of a polynomial threshold function corresponds to Expanded-Winnow’s running time, and the weight of a polynomial threshold function corresponds to its sample complexity.

4 Constructing Polynomial Threshold Functions for Decision Lists

In previous constructions of polynomial threshold functions for computational learning theory applications [20, 19, 50] the sole goal has been to minimize the degree of the polynomials regardless of the size of the coefficients. As an extreme example, the construction of [20] of \( \tilde{O}(n^{1/3}) \) degree polynomial threshold functions for DNF formulae yields polynomials whose coefficients can be doubly exponential in the degree. In contrast, given Theorem 2 we must now construct polynomial threshold functions that have low degree and low weight.

We give two constructions of polynomial threshold functions for decision lists, each of which has relatively low degree and relatively low weight. We then combine these approaches to achieve an optimal construction with improved bounds on both degree and weight.
4.1 Outer Construction

Let $L$ be a decision list of length $k$ over variables $x_1, \ldots, x_k$. We first give a simple construction of a degree $h$, weight $\frac{2^k}{h}2^{(k+h)}$ polynomial threshold function for $L$ which is based on breaking the list $L$ into sublists. We call this construction the “outer construction” since we will ultimately combine this construction with a different construction for the “inner” sublists.

We begin by showing that $L$ can be expressed as a threshold of modified decision lists which we now define. The set $\mathcal{B}_h$ of modified decision lists is defined as follows: each function in $\mathcal{B}_h$ is a decision list $(\ell_1, b_1), (\ell_2, b_2), \ldots, (\ell_h, b_h), 0$ where each $\ell_i$ is some literal over $x_1, \ldots, x_n$ and each $b_i \in \{-1, 1\}$. Thus the only difference between a modified decision list $f \in \mathcal{B}_h$ and a normal decision list of length $h$ is that the final output value is 0 rather than $b_{h+1} \in \{-1, +1\}$.

Without loss of generality we may suppose that the list $L$ is $(x_1, b_1), \ldots, (x_k, b_k), b_{k+1}$. We break $L$ sequentially into $k/h$ blocks each of length $h$. Let $f_i \in \mathcal{B}_h$ be the modified decision list which corresponds to the $i$-th block of $L$, i.e. $f_i$ is the list $(x_{(i-1)h+1}, b_{(i-1)h+1}), \ldots, (x_{(i+1)h}, b_{(i+1)h}), 0$. Intuitively $f_i$ computes the $i$th block of $L$ and equals 0 only if we “fall of the edge” of the $i$th block. We then have the following straightforward claim:

Claim 5 The decision list $L$ is equivalent to

$$\text{sign} \left( \sum_{i=1}^{k/h} 2^{k/h-i+1} f_i(x) + b_{k+1} \right).$$

Proof: Given an input $x \neq 0^k$ let $r = (i-1)h+c$ be the first index such that $x_r$ is satisfied. It is easy to see that $f_j(x) = 0$ for $j < i$ and hence the value in (1) is $2^{k/h-i+1} b_r + \sum_{j=i+1}^{k/h} 2^{k/h-j+1} f_j(x) + b_{k+1}$, the sign of which is easily seen to be $b_r$. Finally if $x = 0^k$ then the argument to (1) is $b_{k+1}$. \[\square\]

Note: It is easily seen that we can replace the 2 in formula (1) by a 3; this will prove useful later.

As an aside, note that Claim 5 can already be used to obtain a tradeoff between running time and sample complexity for learning decision lists. The class $\mathcal{B}_h$ contains at most $(4n)^h$ functions. Thus as in Section 3 it is possible to run the Winnow algorithm using the functions in $\mathcal{B}_h$ as the base features for Winnow. (So for each example $x$ which it receives, the algorithm would first compute the value of $f(x)$ for each $f \in \mathcal{B}_h$, and would then use this vector of $(f(x))_{f \in \mathcal{B}_h}$ values as the example point for Winnow.) A direct analogue of Theorem 2 now implies that Expanded-Winnow (run over this expanded feature space of functions from $\mathcal{B}_h$) can be used to learn $L_k$ in time $n^{O(h)}2^{O(k/h)}$ with mistake bound $2^{O(k/h)h \log n}$.

However, it will be more useful for us to obtain a polynomial threshold function for $L$. We can do this from Claim 5 as follows:

Theorem 6 Let $L$ be a decision list of length $k$. Then for any $h < k$ we have that $L$ is computed by a polynomial threshold function of degree $h$ and weight $4 \cdot 2^{k/h} + h$.

Proof: Consider the first modified decision list $f_1 = (\ell_1, b_1), (\ell_2, b_2), \ldots, (\ell_h, b_h), 0$ in the expression (1). For $\ell$ a literal let $\bar{\ell}$ denote $x$ if $\ell$ is an unnegated variable $x$ and let $\bar{\ell}$ denote $1-x$ if $\ell$ is a negated variable $\bar{x}$. We have that for all $x \in \{0, 1\}^h$, $f_1(x)$ is computed exactly by the polynomial

$$f_1(x) = \bar{\ell}_1 b_1 + (1 - \bar{\ell}_1)\bar{\ell}_2 b_2 + (1 - \bar{\ell}_1)(1 - \bar{\ell}_2)\bar{\ell}_3 b_3 + \cdots + (1 - \bar{\ell}_1) \cdots (1 - \bar{\ell}_{h-1})\bar{\ell}_h b_h.$$

This polynomial has degree $h$ and has weight at most $2^{h+1}$. Summing these polynomial representations for $f_1, \ldots, f_{k/h}$ as in (1) we see that the resulting polynomial threshold function given by (1) has degree $h$ and weight at most $2^{k/h} \cdot 2^{h+1} = 4 \cdot 2^{k/h} + h$. \[\square\]
We will construct a lower (roughly degree $d$) polynomial with weight $P$ then $Q$. Then $L$ is computed by a polynomial threshold function of degree $k^{1/2}$ and weight $4 \cdot 2^{2k^{1/2}}$.

We close this section by observing that an intermediate result of [20] can be used to give an alternate proof of Corollary 7 with slightly weaker parameters; see Appendix A.

### 4.2 Inner Approximator

In this section we construct low degree, low weight polynomials which approximate (in the $L_\infty$ norm) the modified decision lists from the previous subsection. Moreover, the polynomials we construct are exactly correct on inputs which “fall off the end”:

**Theorem 8** Let $f \in B_h$ be a modified decision list of length $h$ (without loss of generality we may assume that $f$ is $(x_1b_1), \ldots, (x_h, b_h), 0$). Then there is a degree $2\sqrt{h} \log h$ polynomial $p$ such that

- for every input $x \in \{0, 1\}^h$ we have $|p(x) - f(x)| \leq 1/h$.
- $p(0^h) = f(0^h) = 0$.

**Proof:** As in the proof of Theorem 6, we have that

$$f(x) = b_1x_1 + b_2(1-x_1)x_2 + \cdots + b_h(1-x_1)\cdots(1-x_{h-1})x_h.$$  

We will construct a lower (roughly $\sqrt{h}$) degree polynomial which closely approximates $f$. Let $T_i$ denote $(1-x_1)\cdots(1-x_{i-1})x_i$, so we can rewrite $f$ as

$$f(x) = b_1T_1 + b_2T_2 + \cdots + b_hT_h.$$  

We approximate each $T_i$ separately as follows: set $A_i(x) = h - i + x_i + \sum_{j=1}^{i-1}(1-x_j)$. Note that for $x \in \{0, 1\}^h$, we have $T_i(x) = 1$ iff $A_i(x) = h$ and $T_i(x) = 0$ iff $0 \leq A_i(x) \leq h - 1$. Now define the polynomial

$$Q_i(x) = q(A_i(x)/h) \quad \text{where} \quad q(y) = C_d(y(1+1/h)).$$  

As in [20], here $C_d(x)$ is the $d$th Chebyshev polynomial of the first kind (a univariate polynomial of degree $d$) with $d$ set to $\sqrt{h}$. We will need the following facts about Chebyshev polynomials [11]:

- $|C_d(x)| \leq 1$ for $|x| \leq 1$ with $C_d(1) = 1$.
- $C'_d(x) \geq d^2$ for $x > 1$ with $C'_d(1) = d^2$.
- The coefficients of $C_d$ are integers each of whose magnitude is at most $2^d$.

These first two facts imply that $q(1) \geq 2$ but $|q(y)| \leq 1$ for $y \in [0, 1 - 1/h]$. We thus have that $Q_i(x) = q(1) \geq 2$ if $T_i(x) = 1$ and $|Q_i(x)| \leq 1$ if $T_i(x) = 0$. Now define $P_i(x) = (\frac{Q_i(x)}{q(1)})^{2\log h}$. This polynomial is easily seen to be a good approximator for $T_i$: if $x \in \{0, 1\}^h$ is such that $T_i(x) = 1$ then $P_i(x) = 1$, and if $x \in \{0, 1\}^h$ is such that $T_i(x) = 0$ then $|P_i(x)| < (\frac{1}{2})^{2\log h} < \frac{1}{h^2}$.

Now define $R(x) = \sum_{i=1}^h b_iP_i(x)$ and $p(x) = R(x) - R(0^h)$. It is clear that $p(0^h) = 0$. We will show that for every input $0^h \neq x \in \{0, 1\}^h$ we have $|p(x) - f(x)| \leq 1/h$. Fix some such $x$; let $i$ be the first index such that $x_i = 1$. As shown above we have $P_i(x) = 1$. Moreover, by inspection of
$T_j(x)$ we have that $T_j(x) = 0$ for all $j \neq i$, and hence $|P_j(x)| < \frac{1}{h^j}$. Consequently the value of $R(x)$ must lie in $[b_i - \frac{4}{h^j}, b_i + \frac{4}{h^j}]$. Since $f(x) = b_i$ we have that $p(x)$ is an $L_\infty$ approximator for $f(x)$ as desired.

Finally, it is straightforward to verify that $p(x)$ has the claimed bound on degree. \qed 

Strictly speaking we cannot discuss the weight of the polynomial $p$ since its coefficients are rational numbers but not integers. However, by multiplying $p$ by a suitable integer (clearing denominators) we obtain an integer polynomial with essentially the same properties. Using the third fact about Chebyshev polynomials from our proof above, we have that $q(1)$ is a rational number $N_1/N_2$ where $N_1, N_2$ are each integers of magnitude $h^{O(\sqrt{h})}$. Each $Q_i(x)$ for $i = 1, \ldots, h$ can be written as an integer polynomial (of weight $h^{O(\sqrt{h})}$) divided by $h^{\sqrt{h}}$. Thus each $P_i(x)$ can be written as $\tilde{P}_i(x)/(h^{\sqrt{h}}N_1)^{2\log h}$ where $\tilde{P}_i(x)$ is an integer polynomial of weight $h^{O(\sqrt{h}\log h)}$. It follows that $p(x)$ equals $\tilde{p}(x)/C$, where $C$ is an integer which is at most $2^{O(h^{1/2}\log^2 h)}$ and $\tilde{p}$ is a polynomial with integer coefficients and weight $2^{O(h^{1/2}\log^2 h)}$. We thus have

Corollary 9 Let $f \in B_h$ be a modified decision list of length $h$. Then there is an integer polynomial $p(x)$ of degree $2\sqrt{h}\log h$ and weight $2^{O(h^{1/2}\log^2 h)}$ and an integer $C = 2^{O(h^{1/2}\log^2 h)}$ such that

- for every input $x \in \{0, 1\}^h$ we have $|p(x) - Cf(x)| \leq C/h$.
- $p(0^h) = f(0^h) = 0$.

The fact that $p(0^h)$ is exactly 0 will be important in the next subsection when we combine the inner approximator with the outer construction.

4.3 Composing the Constructions

In this section we combine the two constructions from the previous subsections to obtain our main polynomial threshold construction:

Theorem 10 Let $L$ be a decision list of length $k$. Then for any $h < k$, $L$ is computed by a polynomial threshold function of degree $O(h^{1/2}\log h)$ and weight $2^{O(k/h + h^{1/2}\log^2 h)}$.

Proof: We suppose without loss of generality that $L$ is the decision list $(x_1, b_1), \ldots, (x_k, b_k), b_{k+1}$. We begin with the outer construction: from the note following Claim 5 we have that

$$L(x) = \text{sign} \left( C \sum_{i=1}^{k/h} 3^{k/h - i + 1} f_i(x) + b_{k+1} \right)$$

where $C$ is the value from Corollary 9 and each $f_i$ is a modified decision list of length $h$ computing the restriction of $L$ to its $i$th block as defined in Subsection 4.1. Now we use the inner approximator to replace each $Cf_i$ above by $p_i$, the approximating polynomial from Corollary 9, i.e. consider $\text{sign}(H(x))$ where

$$H(x) = \sum_{i=1}^{k/h} (3^{k/h - i + 1} p_i(x)) + Cb_{k+1}.$$ 

We will show that $\text{sign}(H(x))$ is a polynomial threshold function which computes $L$ correctly and has the desired degree and weight.

Fix any $x \in \{0, 1\}^k$. If $x = 0^k$ then by Corollary 9 each $p_i(x)$ is 0 so $H(x) = Cb_{k+1}$ has the right sign. Now suppose that $r = (i - 1)h + c$ is the first index such that $x_r = 1$. By Corollary 9 we have that
\begin{itemize}
\item $3^{k/h-j+1} p_j(x) = 0$ for $j < i$;
\item $3^{k/h-i+1} p_i(x)$ differs from $3^{k/h-i+1} C_b$ by at most $C 3^{k/h-i+1} \cdot \frac{1}{h}$;
\item The magnitude of each value $3^{k/h-j+1} p_j(x)$ is at most $C 3^{k/h-j+1} (1 + \frac{1}{h})$ for $j > i$.
\end{itemize}

Combining these bounds, the value of $H(x)$ differs from $3^{k/h-i+1} C_b$ by at most

\[
C \left( \frac{3^{k/h-i+1}}{h} + \left( 1 + \frac{1}{h} \right) \left[ 3^{k/h-i} + 3^{k/h-i-1} + \cdots + 3 \right] + 1 \right)
\]

which is easily seen to be less than $C 3^{k/h-i+1}$ in magnitude. Thus the sign of $H(x)$ equals $b_r$, and consequently $\text{sign}(H(x))$ is a valid polynomial threshold representation for $L(x)$. Finally, our degree and weight bounds from Corollary 9 imply that the degree of $H(x)$ is $O(h^{1/2} \log h)$ and the weight of $H(x)$ is $2^{O(k/h) + O(h^{1/2} \log^2 h)}$, and the theorem is proved. \hfill $\Box$

Taking $h = k^{2/3} / \log^{4/3} k$ in the above theorem we obtain our main result on representing decision lists as polynomial threshold functions:

**Theorem 3** Let $L$ be a decision list of length $k$. Then $L$ is computed by a polynomial threshold function of degree $k^{1/3} \log^{1/3} k$ and weight $2^{O(k^{1/3} \log^{4/3} k)}$.

Theorem 3 immediately implies that Expanded-Winnow can learn decision lists of length $k$ using $2^{O(k^{1/3})}$ log $n$ examples and time $n \tilde{O}(k^{1/3})$.

### 5 Application to Learning Decision Trees

In 1989 Ehrenfeucht and Haussler [13] gave an $n^{O(\log s)}$ algorithm for learning decision trees of size $s$ over $n$ variables. Their algorithm uses $n^{O(\log s)}$ examples, and they asked if the sample complexity could be reduced to poly($n, s$). We can apply our techniques here to give an algorithm using $2^{O(s^{1/3})} \log n$ examples, if we are willing to spend $n^{\tilde{O}(s^{1/3})}$ time.

First we need to generalize Theorem 10 for higher order decision lists. An $r$-decision list is like a standard decision list but each pair is now of the form $(C_i, b_i)$ where $C_i$ is a conjunction of at most $r$ literals and as before $b_i = \pm 1$. The output of such an $r$-decision list on input $x$ is $b_i$ where $i$ is the smallest index such that $C_i(x) = 1$.

We have the following:

**Corollary 11** Let $L$ be an $r$-decision list of length $k$. Then for any $h < k$, $L$ is computed by a polynomial threshold function of degree $O(r h^{1/2} \log h)$ and weight $2^r + O(k/h + h^{1/2} \log^2 h)$.

**Proof:** Let $L$ be the $r$-decision list $(C_1, b_1), \ldots, (C_k, b_k), b_{k+1}$. By Theorem 10 there is a polynomial threshold function of degree $O(h^{1/2} \log h)$ and weight $2^O(k/h + h^{1/2} \log^2 h)$ over the variables $C_1, \ldots, C_k$. Now replace each variable $C_i$ by the interpolating polynomial which computes it exactly as a function from $\{0, 1\}^n$ to $\{0, 1\}$. Each such interpolating polynomial has degree $r$ and integer coefficients of total magnitude at most $2^r$, and the corollary follows. \hfill $\Box$

**Corollary 12** There is an algorithm for learning $r$-decision lists over $\{0, 1\}^n$ which, when learning an $r$-decision list of length $k$, has mistake bound $2^{O(r+k^{1/3})} \log n$ and runs in time $n^{\tilde{O}(r^{1/3})}$. 

10
Proof: Blum [5] has shown that any decision tree of size $s$ over $n$ variables. Then D can be learned using $2^{O(n^{1/3}) \log n}$ examples in time $n^{O(n^{1/3})}$.

**Theorem 13** Let $D$ be a decision tree of size $s$ over $n$ variables. Then $D$ can be learned using $2^{O(s^{1/3}) \log n}$ examples in time $n^{O(s^{1/3})}$.

**Proof:** Blum [5] has shown that any decision tree of size $s$ is computed by a (log $s$)-decision list of length $s$. Applying Corollary 12 we thus see that Expanded-Winnow can be used to learn decision trees of size $s$ over $\{0,1\}^n$ with the claimed bounds on time and sample complexity. □

### 6 Lower Bounds for Decision Lists

Here we observe that our construction from Theorem 10 is essentially optimal in terms of the tradeoff it achieves between polynomial threshold function degree and weight.

In [3], Beigel constructs an oracle separating $PP$ from $P^{NP}$. At the heart of his construction is a proof that any low degree polynomial threshold function for a particular decision list, called the ODDMAXBIT$_n$ function, must have large weights:

**Definition 14** The ODDMAXBIT$_n$ function on input $x = x_1, \ldots, x_n \in \{0,1\}^n$ equals $(-1)^i$ where $i$ is the index of the first nonzero bit in $x$.

It is clear that the ODDMAXBIT$_n$ function is equivalent to a decision list of length $n$:

$$(x_1, -1), (x_2, 1), (x_3, -1), \ldots, (x_n, (-1)^n), (-1)^{n+1}.$$ 

The main technical theorem which Beigel proves in [3] states that any polynomial threshold function of degree $d$ computing ODDMAXBIT$_n$ must have weight $2^{O(n/d^2)}$.

**Theorem 15** Let $p$ be a degree $d$ polynomial threshold function with integer coefficients computing ODDMAXBIT$_n$. Then $w = 2^{O(n/d^2)}$ where $w$ is the weight of $p$.\(^3\)

(As stated in [3] the bound is actually $w \geq \frac{1}{2}2^{O(n/d^2)}$ where $s$ is the number of nonzero coefficients in $p$. Since $s \leq w$ this implies the result as stated above.)

A lower bound of $2^{\Omega(n)}$ on the weight of any linear threshold function ($d = 1$) for ODDMAXBIT$_n$ has long been known [28]; Beigel’s proof generalizes this lower bound to all $d = O(n^{1/2})$. A matching upper bound of $2^{O(n)}$ on weight for $d = 1$ has also long been known [28]. Our Theorem 10 gives an upper bound which matches Beigel’s lower bound (up to logarithmic factors) for all $d = O(n^{1/3})$:

**Observation 16** For any $d = O(n^{1/3})$ there is a polynomial threshold function of degree $d$ and weight $2^{O(n/d^2)}$ which computes ODDMAXBIT$_n$.

**Proof:** Set $d = h^{1/2} \log h$ in Theorem 10. The weight bound given by Theorem 10 is $2^{O(n \log^2 d/d^2 + d \log d)}$ which is $\tilde{O}(n/d^2)$ for $d = O(n^{1/3})$. □

Note that since the ODDMAXBIT$_n$ function has a polynomial size DNF (see Appendix A), Beigel’s lower bound gives a polynomial size DNF $f$ such that any degree $\tilde{O}(n^{1/3})$ polynomial threshold function for $f$ must have weight $2^{\Omega(n^{1/3})}$. This suggests that the Expanded-Winnow algorithm cannot learn polynomial size DNF in $2^{\tilde{O}(n^{1/3})}$ time from $2^{n^{1/3-\epsilon}}$ examples for any $\epsilon > 0$, and thus suggests that improving the sample complexity of the DNF learning algorithm from [20] while maintaining its $2^{\tilde{O}(n^{1/3})}$ running time may be difficult.

\(^3\)Beigel actually proves something stronger, namely that there must exists a coefficient whose absolute value is at least $2^{\tilde{O}(n/d^2)}$. 

11
7 Learning Parity Functions

We first briefly review the standard algorithm for learning parity functions.

The standard algorithm for learning parity functions works by viewing a set of $m$ labelled examples as a set of $m$ linear equations over GF(2). Each labelled example $(x, b)$ induces the equation $\sum_{x_i=1} a_i = b \mod{2}$. Since the examples are labelled according to some parity function, this parity function will be a consistent solution to the system of equations. Using Gaussian elimination it is possible to efficiently find a solution to the linear system, which yields a parity function consistent with all $m$ examples. The following standard fact from learning theory (often referred to as “Occam’s Razor”) shows that finding a consistent hypothesis suffices to establish PAC learnability:

**Fact 17** Let $C$ be a concept class and $H$ a finite set of hypotheses. Set $m = 1/\epsilon \left( \log |H| + \log 1/\delta \right)$ where $\epsilon$ and $\delta$ are the usual accuracy and confidence parameters for PAC learning. Suppose that there is an algorithm $A$ running in time $t$ which takes as input $m$ examples which are labelled according to some element of $C$ and outputs a hypothesis $h \in H$ consistent with these examples. Then $A$ is a PAC learning algorithm for $C$ with running time $t$ and sample complexity $m$.

Consider using the above algorithm to learn an unknown parity of length at most $k$. Even though there is a solution of weight at most $k$, Gaussian elimination (applied to a system of $m$ equations in $n$ variables over GF(2)) may yield a solution of weight as large as $\min(m, n)$. Using Fact 17 we thus obtain a sample complexity bound of $O(n)$ examples for learning a parity of length at most $k$.

We now present a simple polynomial-time algorithm for learning an unknown parity function on $k$ variables using $O(n^{1-1/k})$ examples. To the best of our knowledge this is the first improvement on the standard algorithm and analysis given above.

**Theorem 18** The class of all parity functions on at most $k$ variables is learnable in polynomial time using $O(n^{1-1/k}\log n)$ examples. The hypothesis output by the learning algorithm is a parity function on $O(n^{1-1/k}\log n)$ variables.

**Proof:** If $k = \Omega(\log n)$ then the standard algorithm suffices to prove the claimed bound. We thus assume that $k = o(\log n)$.

Let $H$ be the set of all parity functions of size at most $n^{1-1/k}$. Note that $|H| \leq n^{n^{1-1/k}}$ so $\log |H| \leq n^{1-1/k} \log n$. Consider the following algorithm:

1. Choose $m = 1/\epsilon \left( \log |H| + \log(1/\delta) \right)$ examples. Express each example as a linear equation over $n$ variables mod 2 as described above.

2. Randomly choose a set of $n - n^{1-1/k}$ variables and assign them the value 0.

3. Use Gaussian elimination to attempt to solve the resulting system of equations on the remaining $n^{1-1/k}$ variables. If the system has a solution, output the corresponding parity (of size at most $n^{1-1/k}$) as the hypothesis. If the system has no solution, output “FAIL.”

If the simplified system of equations has a solution, then by Fact 17 this solution is a good hypothesis. We will show that the simplified system has a solution with probability $\Omega(1/n)$. The theorem follows by repeating steps 2 and 3 of the above algorithm until a solution is found (an expected $O(n)$ repetitions will suffice).

Let $V$ be the set of $k$ relevant variables on which the unknown parity function depends. It is easy to see that as long as no variable in $V$ is assigned a 0, the resulting simplified system of
equations will have a solution. Let $\ell = n^{1-1/k}$. The probability that in Step 2 the $n - \ell$ variables chosen do not include any variables in $V$ is exactly $\binom{n-k}{n-\ell}/\binom{n}{\ell}$ which equals $\binom{n-k}{n-\ell}/\binom{n}{\ell}$. Expanding binomial coefficients we have

$$\binom{n-k}{n-\ell} = \frac{k}{\ell} \prod_{i=1}^{k} \frac{\ell - k + i}{n - k + i} > \left( \frac{\ell - k}{n - k} \right)^k = \left( \frac{\ell}{n} \right)^k \left( \frac{1 - k}{1 - k/n} \right)^k = \frac{1}{n^k} \left[ \left( 1 - \frac{k}{n} \right) \left( 1 + \frac{2k}{n} \right) \right]^k. \quad (2)$$

The bound $k = o(\log n)$ implies that $\left( 1 - \frac{k}{n} \right) \left( 1 + \frac{2k}{n} \right) > (1 - \frac{3k}{n})$. Consequently (2) is at least $\frac{1}{n} \cdot (1 - \frac{3k^2}{n}) > \frac{1}{2n}$ and the theorem is proved.

## 8 Future Work

An obvious goal for future work is to improve our algorithmic results for learning decision lists. The question still remains: can decision lists of length $k$ be learned in $\text{poly}(n)$ time from $\text{poly}(k, \log n)$ examples? As a first step, one might attempt to extend the tradeoffs we achieve: is it possible to learn decision lists of length $k$ in $n^{1/2}$ time from poly$(k, \log n)$ examples?

Another goal is to extend our results for decision lists to broader concept classes. In particular, since decision lists are a special case of linear threshold functions, it would be interesting to obtain analogues of our algorithmic results for learning general linear threshold functions (independent of their weight). We note here that Goldmann et al. [15] have given a linear threshold function over $\{-1,1\}^n$ for which any polynomial threshold function must have weight $2^{\Omega(n^{1/2})}$ regardless of its degree. Moreover Krause and Pudlak [21] have shown that any Boolean function which has a polynomial threshold function over $\{0,1\}^n$ of weight $w$ has a polynomial threshold function over $\{-1,1\}^n$ of weight $n^2w^4$. These results imply that representation results akin to Theorem 3 for general linear threshold functions must be quantitatively weaker than Theorem 8; in particular, there is a linear threshold function over $\{0,1\}^n$ with $k$ nonzero coefficients for which any polynomial threshold function, regardless of degree, must have weight $2^{\Omega(k^{1/2})}$.

For parity functions, one challenge is to learn parity functions on $k = \Theta(\log n)$ variables in polynomial time using a sublinear number of examples. Another challenge is to improve the sample complexity of learning size $k$ parities from our current bound of $O(n^{1-1/k})$.

## 9 Acknowledgements

We thank Les Valiant for his observation that Claim 5 can be reinterpreted in terms of polynomial threshold functions. We thank Jean Kwon for suggesting the Chebychev polynomial.

A Alternate Proof of Corollary 7

The alternate proof of Corollary 7 is based on the observation that any decision list \( L = (\ell_1, b_1), \ldots, (\ell_k, b_k), b_{k+1} \) of length \( k \) has a \( k \)-term DNF in which each term is a conjunction of at most \( k \) literals. To see this, note that we obtain a DNF for \( L \) simply by taking the OR of all terms \( \ell_1 \ell_2 \ldots \ell_{i-1} \ell_i \) for each \( i \) such that \( b_i = 1 \). Now we use the following result from [20]:

**Theorem 19 (Corollary 12 of [20])** Let \( f \) be a DNF formula of \( s \) terms, each of length at most \( t \). Then there is a polynomial threshold function for \( f \) of degree \( O(\sqrt{t} \log s) \) and weight \( t^{O(\sqrt{t} \log s)} \).

Applying this result to the DNF representation for \( L \), we immediately obtain that there is a polynomial threshold function for \( L \) which has degree \( O(k^{1/2} \log k) \) and weight \( 2^{O(k^{1/2} \log^2 k)} \). (In Section 4.2, though, we need the construction given in our original proof of Corollary 7.)
