**ABSTRACT**

One of the most essential but uncertain processes for producing cosmic rays (CRs) and their spectra is how accelerated particles escape into the interstellar space. We propose that the CR electron spectra at \( \gtrsim \) TeV energies can provide a direct probe of the CR escape complementary to the CR nuclei and gamma rays. We calculate the electron spectra from a young pulsar embedded in a supernova remnant (SNR), like Vela, taking into account the energy-dependent CR escape. SNRs would accelerate and hence confine particles with energies up to \( 10^{15.5} \) eV. Only energetic particles can escape first, while the lower energy particles are confined and released later. Then the observed electron spectrum should have a low-energy cutoff the position of which marks the age of the pulsar/SNR. The low-energy cutoff is observable in the \( \gtrsim \) TeV energy window, where other contaminating sources are expected to be few due to the fast cooling of electrons. The spectrum looks similar to a dark matter annihilation line if the low-energy cutoff is close to the high-energy intrinsic or cooling break. Future experiments, such as the Calorimetric Electron Telescope and Cherenkov Telescope Array, are capable of directly detecting the CR escape features toward revealing the origin of CRs.

1. **INTRODUCTION**

The origin of cosmic rays (CRs) has been a long-standing problem since its discovery. The number spectrum of the nuclear component of CRs can be fitted with a broken power law: \( N(\varepsilon) \propto \varepsilon^{-s} \) with \( s \approx 2.7 \) below \( \varepsilon \approx 10^{15.5} \) eV (the “knee” energy). The charged CR particles are considered to propagate diffusively in an energy-dependent manner (the higher energy particles can diffuse faster), so the intrinsic CR spectrum at the source should be harder than that observed at the Earth. Although there are some ambiguities in the energy dependence on the diffusion coefficient, the source spectral index is considered to be around \( s \approx 2.2 \) (e.g., Strong & Moskalenko 1998).

It is often argued that CRs with energies smaller than the knee energy (or even up to \( 10^{18} \) eV) originated in our Galaxy. The most widely accepted paradigm for the galactic CR production process is the diffusive shock acceleration (DSA) at supernova remnants (SNRs). The theory of DSA (for reviews, see Blandford & Eichler 1987; Malkov & Drury 2001) can naturally derive the power-law spectrum of particles accelerated at the shock with a large Mach number is \( s = 2 \) and harder than that expected from the observations. Moreover, the nonlinear theories of DSA predict a harder source spectrum \( s \lesssim 2.0 \), which seems to make the contradiction between theories and observations even worse.

It has been proposed that these observational facts can be interpreted by the model of the energy-dependent CR escape from the SNR (Ptuskin & Zirakashvili 2005; Drury et al. 2009; Reville et al. 2009; Caprioli et al. 2009; Gabici et al. 2009; Ohira et al. 2010; Fujita et al. 2010; Casanova et al. 2010). In the escape model it is assumed that the most energetic particles leave the SNR at the beginning of the Sedov phase and, as the shock slows down and the magnetic field decays, the lower energy particles, which have been confined around the shock front by the magnetic field, can leave the shock gradually. This process can largely affect the CR spectrum detected at the Earth (Ohira et al. 2010; Caprioli et al. 2010). In fact, the spectral index of the CR escaping the SNR (\( s_{\text{esc}} \)) is different from that of the CR inside the SNR (\( s \)),

\[ s_{\text{esc}} = s + \frac{\beta}{\alpha} , \]

where the escape energy \( \varepsilon_{\text{esc}} \) and the normalization factor of the CR production rate are assumed to be proportional to \( t^{-\alpha} \) and \( t^\beta \), respectively. For example, in the phenomenological model by Gabici et al. (2009) \( \alpha \sim 2.6 \) (see also Ohira et al. 2010). Therefore, the observed spectral index can get softer than the conventional value \( s \approx 2 \) if the normalization factor of the spectrum gets larger with time (i.e., \( \beta > 0 \); Ohira et al. 2010), so we may interpret the observed CR spectrum in the context of DSA with the escape model. Moreover, recent gamma-ray observations by Fermi and AGILE of middle-aged SNRs interacting with molecular clouds show that those spectra are fitted by a broken power law with a break energy of \( \sim 1 \)–\( 10 \) GeV (see the references shown above), and they can be interpreted as energy-dependent CR escape from an SNR (Aharonian & Atoyan 1996; Gabici et al. 2009; Ohira et al. 2011).³ However, recent some authors have tried to explain this spectral break by considering the other processes such as the propagation of the SNR shock in the molecular clouds (Uchiyama et al. 2010) or the two-step acceleration of CR particles by the shocks generated by the turbulence behind the SNR shock (Inoue et al. 2010).

³ Recently some authors have tried to explain this spectral break by considering the other processes such as the propagation of the SNR shock in the molecular clouds (Uchiyama et al. 2010) or the two-step acceleration of CR particles by the shocks generated by the turbulence behind the SNR shock (Inoue et al. 2010).
these gamma rays are the secondary emissions of CRs from an SNR, and so these observations are only indirect evidences of the CR escape scenario.

On the other hand, the direct observations of CR electrons/positrons have also been greatly advanced. The PAMELA satellite discovered the excess of the CR positron fraction (Adriani et al. 2009) and, as for the flux of CR electrons plus positrons, the experiments such as ATIC/PPB-BETS (Chang et al. 2008; Torii et al. 2008b), Fermi (Abdo et al. 2009a; Ackermann et al. 2010), and HESS (Aharonian et al. 2008, 2009) have revealed an excess from the conventional model (see also Meyer et al. 2010 for the energy calibration between Fermi and HESS). These results suggest that there are some additional electron/positron sources. Possible candidates include astrophysical sources such as pulsars (Shen 1970; Atoyan et al. 1995; Chi et al. 1996; Zhang & Cheng 2001; Grimani 2007; Kobayashi et al. 2004; Büsching et al. 2008; Hooper et al. 2009; Yuksel et al. 2009; Profumo 2008; Malyshev et al. 2009; Grasso et al. 2009; Kawanaka et al. 2010; Heyl et al. 2010; Blasi & Amato 2010), SNRs (Shaviv et al. 2009; Blasi 2009; Blasi & Serpico 2009; Fujita et al. 2009; Hu et al. 2009; Biermann et al. 2009; Mertsch & Sarkar 2009; Ahlers et al. 2009), gamma-ray bursts (GRBs; Ioka 2010; Kistler & Yuksel 2009), microquasars (Heinz & Sunyaev 2002), and white dwarf pulsars (Kashiyama et al. 2011). Dark matter annihilations/decays (e.g., Hooper 2009) and the propagation effect (Delahaye et al. 2008; Cowsk & Burch 2010; Stawarz et al. 2010) are also possible processes for making the CR electron/positron excess (for a comprehensive review, see Fan et al. 2010).

In the near future, within a few years, the Alpha Magnetic Spectrometer-02 (AMS-02) experiment will measure the positron fraction up to \( \sim 1 \text{TeV} \) (Beischer et al. 2009; Pato et al. 2010; Pochon 2010) and the Calorimetric Electron Telescope (CALET) experiment will explore the electron spectrum\(^4\) up to \( \sim 10 \text{TeV} \) with an energy resolution better than a few percent (Torii et al. 2008a). In addition, the future Cherenkov Telescope Array (CTA) will be able to measure the CR electron spectrum up to \( \sim 15 \text{TeV} \) (CTA Consortium 2010). These experiments will open the window to CR astrophysics with TeV electron and positron components. Specifically, as Kobayashi et al. (2004) have pointed out, in the TeV energy band a few nearby sources may leave spectral signatures, and we will be able to see the spectral shape of CR electrons/positrons from a single source, while in the lower energy band we can see only the superposed spectrum from multiple sources.

In this paper, we suggest a possibility that the precise measurement of the CR electron spectrum in the very high energy band (\( \gtrsim 10^{-3} \text{TeV} \), expected with CALET and CTA) could directly prove the energy-dependent CR escape if those electrons/positrons are generated by a pulsar embedded in an SNR. This is quite a natural situation to be realized because a pulsar should be generated in the center of a core-collapse supernova, and CR electrons/positrons are considered to be generated in the pulsar wind nebula (PWN) formed inside the SNR. If the CR escape really occurs in a young nearby pulsar/SNR system, the electron spectrum from it will show a unique feature as explained in the following and, when it is observed, it will be the first direct evidence of the CR escape scenario.

\(^4\) Hereafter we express the spectrum of electrons plus positrons as just “electron spectrum.”

### 2. A SIMPLE EXAMPLE

To illustrate our main idea, we show a clear example of the effect of the energy-dependent CR escape in direct electron observations. In the calculations of CR electrons/positrons, we usually assume that they are injected into the interstellar matter (ISM) from a pulsar with the spectral form of

\[
Q_{\text{e}}(\varepsilon_{\text{e}}) = Q_{0}\varepsilon_{\text{e}}^{-\alpha},
\]

where \( \varepsilon_{\text{e}} \) is the energy of electrons/positrons. The observed electron spectrum \( f(\varepsilon_{\text{e}}, r, t) \) can be obtained by solving the diffusion equation

\[
\frac{\partial}{\partial t} f = D(\varepsilon_{\text{e}}) \nabla^2 f + \frac{\partial}{\partial \varepsilon_{\text{e}}} [P(\varepsilon_{\text{e}}) f] + Q_{\text{e}}(\varepsilon_{\text{e}}, r, t),
\]

where \( D(\varepsilon_{\text{e}}) = D_0 (1 + \varepsilon_{\text{e}}/3 \text{GeV})^{\delta} \) is the diffusion coefficient and \( P(\varepsilon_{\text{e}}) \) is the energy loss rate. Here we adopt \( D_0 = 5.8 \times 10^{23} \text{cm}^2 \text{s}^{-1} \), \( \delta = 1/3 \), which is consistent with the boron-to-carbon ratio according to the latest GALPROP code, and \( P(\varepsilon_{\text{e}}) = -b\varepsilon_{\text{e}}^2 \) with \( b = 10^{-16} \text{GeV}^{-1} \text{s}^{-1} \), which includes the energy loss via synchrotron emission and inverse Compton scatterings (with Thomson approximation). Then, if electrons/positrons are injected from a point-like source instantaneously (i.e., \( Q_{\text{e}}(\varepsilon_{\text{e}}, r, t) \propto \delta(t)\delta(r) \)), the observed spectrum is simply written as

\[
f \sim \frac{Q_0\varepsilon_{\text{e}}^{-\alpha}}{\pi^{3/2}d_{\text{diff}}^2} (1 - bt\varepsilon_{\text{e}})^{-2} e^{-r/(d_{\text{diff}})^2},
\]

where \( d_{\text{diff}} \sim \sqrt{4D(\varepsilon_{\text{e}})T} \) is the diffusion length of CR electrons/positrons. This spectrum is roughly proportional to \( \varepsilon_{\text{e}}^{-3/2} \exp(-r^2/(4D(\varepsilon_{\text{e}})T)) \) up to the sharp cutoff at \( \varepsilon_{\text{e}} \sim 1/(bt) \) and exponentially damps beyond the diffusion length \( d_{\text{diff}} \) (Atoyan et al. 1995; Ioka 2010).

However, if the energy-dependent escape of CR particles from the shock is taken into account, the electron spectrum would have a sharp cutoff in the low-energy side because lower energy CRs cannot escape into the ISM. The energy of particles which are marginally capable of escaping into the ISM (\( \varepsilon_{\text{esc}} \)) is generally determined by the confinement condition of CR particles, i.e., the equality between the diffusion length of particles and the characteristic size of the system:

\[
l_{\text{diff}} = \frac{D_{\text{sh}}(\varepsilon_{\text{esc}})}{u_{\text{sh}}} \sim R_{\text{sh}},
\]

where \( D_{\text{sh}}, u_{\text{sh}}, \) and \( R_{\text{sh}} \) are the diffusion coefficient around the SNR shock, the shock velocity, and the size of the system, respectively. Then, the energy \( \varepsilon_{\text{esc}} \) is generally a function of time \( t \) due to the evolution of \( D_{\text{sh}}, R_{\text{sh}}, \) and \( u_{\text{sh}} \).

Figure 1 shows the electron spectrum assuming that only electrons and positrons above the escape energy \( \varepsilon_{\text{esc}} \) are injected instantaneously. The energy of electrons/positrons which is initially \( \varepsilon_{\text{esc}} \) becomes \( \varepsilon_{\text{esc}}/(1 + \beta_{\text{esc}}t_{\text{age}}) \) as a result of radiative cooling (where \( t_{\text{age}} \) is the time since the emission), and we can clearly see a sharp cutoff of the spectrum at that energy, which is the effect of the energy-dependent escape of CR particles. If such a spectrum is confirmed by the future experiments, it would strongly support the CR escape scenario of the particle acceleration process at the SNR, and we may also obtain information regarding \( \varepsilon_{\text{esc}} \) at the time of the source age \( t_{\text{age}} \).
3. MODEL OF CR ELECTRON/POSITRON ESCAPE

Let us consider a model more sophisticated than the one discussed in the previous section. We consider a pulsar emitting electrons and positrons embedded in the SNR (i.e., it has not been evacuated by the SNR by the natal kick). A pulsar is considered to be an efficient $e^\pm$ factory because its rotating magnetic field would produce a strong electric field around the pulsar, and then a large number of $e^\pm$ pairs would be produced via electromagnetic cascades. The created pairs would stream away due to a centrifugal force as a pulsar wind ends with a termination shock where the acceleration of electrons/positrons may occur. Hereafter we assume the $e^\pm$ production rate per energy from a pulsar having a spectrum with a cutoff power-law shape as

$$\dot{N}_{\text{e,pr}}(\varepsilon_e, t) = Q_0(t)\varepsilon_e^{-\alpha} \exp \left( -\frac{\varepsilon_e}{\varepsilon_{\text{e,cut}}} \right),$$

where the high-energy break is fixed as $\varepsilon_{\text{e,cut}} = 10^{14}$ TeV. According to the gamma-ray observations of PWNe, the electrons/positrons accelerated up to the energies of $10^{14} - 10^{16}$ TeV seem to exist in the nebulae (e.g., Aharonian et al. 2006), so this assumption is reasonable. Here, $Q_0(t)$ is given to satisfy

$$L_{e,\text{pr}}(t) = \int_{\varepsilon_{\text{min}}}^{\infty} d\varepsilon_e \dot{N}_{e,\text{pr}}(\varepsilon_e, t),$$

where $L_{e,\text{pr}}(t)$ is the electron/positron production luminosity and $\varepsilon_{\text{min}}$ is set to be 1 GeV. We assume that this luminosity is proportional to the spin-down luminosity of the pulsar:

$$L_{e,\text{pr}}(t) \propto \frac{1}{(1 + t/\tau_0)^2},$$

where $\tau_0 \sim 10^7 - 10^8$ yr is the spin-down timescale, which is related to the surface magnetic field of the pulsar (Shapiro & Teukolsky 1983).

In order to evaluate the CR spectrum in the escape scenario, we should assume the time evolution of $\varepsilon_{\text{esc}}$. In this study, we adopt two models for the functional form of $\varepsilon_{\text{esc}}$. In the first model, we assume for $\varepsilon_{\text{esc}}(t)$ a power-law behavior, and determine its normalization and power-law index according to the hypothesis that SNRs are responsible for the observed CRs with energies from $\sim 1$ GeV up to the knee energy ($\sim 10^{15.5}$ GeV).

$$\varepsilon_{\text{esc}}(t) = 10^{5.5}\text{GeV} \times \left( \frac{t}{t_{\text{Sedov}}} \right)^{-2.6}.$$  \hspace{1cm} (9)

As the second model for the evolution of $\varepsilon_{\text{esc}}$, we adopt the one discussed by Ptuskin & Zirakashvili (2005), which takes into account the modification of a shock structure due to the CR pressure, as well as the nonlinear dissipation of magnetic turbulence. They solve the steady-state equation which determines the energy density of the magnetohydrodynamic turbulence $W$:

$$u \nabla W(k) = 2 \left( \Gamma_{\text{cr}}(k) - \Gamma_1(k) - \Gamma_{\text{nl}}(k) \right) W(k),$$

where $u$ is the flow velocity (here it is equal to the shock velocity $u_{\text{sh}}$), $k$ is the wavenumber of the turbulence, and $\Gamma_{\text{cr}}$, $\Gamma_1$, and $\Gamma_{\text{nl}}$ are the wave growth rate at the shock due to the CR streaming instability, and the damping rates of waves in the background plasma due to the ion–neutral and electron–ion collisions (linear damping), and due to the wave–wave interactions (nonlinear damping), respectively. The mathematical expressions for these functions are shown in Ptuskin & Zirakashvili (2005), and by solving this equation (while the linear damping term is neglected), we obtain the threshold particle energy for escape as a function of the shock velocity $u_{\text{sh}}$. Since we know the time dependence of the shock radius and the shock velocity in the Sedov phase, we can derive $\varepsilon_{\text{esc}}(t)$ as a function of time. When the age of the SNR is $\lesssim 10^5$ yr, the evolution of $\varepsilon_{\text{esc}}(t)$ in this model can be approximated as

$$\varepsilon_{\text{esc}}(t) \simeq 10^{5.5}\text{GeV} \times \left( \frac{t}{t_{\text{Sedov}}} \right)^{-1.0}.$$  \hspace{1cm} (11)

Figure 2 shows the evolutions of $\varepsilon_{\text{esc}}(t)$ in two models described above. Once we fix the time dependence of $\varepsilon_{\text{esc}}$, we can describe the number luminosity per energy of escaping electrons and positrons as

$$\dot{N}_{e,\text{esc},1}(\varepsilon_e, t) = \dot{N}_{e,\text{pr}}(\varepsilon_e, t) \Theta(\varepsilon_e - \varepsilon_{\text{esc}}),$$

where $\Theta(x)$ is the step function. There is another flux component which should be taken into account. The electrons/positrons which have energies lower than $\varepsilon_{\text{esc}}(t)$ are confined in the SNR and lose their energy adiabatically (Ptuskin & Zirakashvili 2005). As $\varepsilon_{\text{esc}}(t)$ decreases with time, some of the confined and adiabatically cooled electrons/positrons can escape the shock surface when their energies become greater than $\varepsilon_{\text{esc}}(t)$. First, the CR electron/positron population per energy confined in the SNR can be written as

$$N_{e,\text{conf}}(\varepsilon_e, t) = \int_{t_{\text{Sedov}}}^{t} \dot{N}_{e,\text{pr}}(\varepsilon_e', t') \frac{d\varepsilon_e'}{d\varepsilon_e} \Theta(\varepsilon_{\text{esc}}(t') - \varepsilon_e'),$$

where $\Theta(x)$ is the step function. However, in the usual case the step function is a good approximation (Ptuskin & Zirakashvili 2005; Caprioli et al. 2009).
where $\epsilon'_e$ is the energy of the electrons/positrons at the time $t'$, and it is $\epsilon_e$ at the time $t$.

The adiabatic loss is determined by the expansion law of the SNR,

$$\frac{d\epsilon_e}{dt} = -\frac{\dot{R}_{SNR}}{R_{SNR}} \epsilon_e,$$

where $R_{SNR}$ and $\dot{R}_{SNR}$ are the radius of the SNR shell and its expansion velocity, respectively. In the following we assume that the SNR is in the Sedov phase, in which the time dependence of $R_{SNR}$ is expected to be proportional to $t^{2/5}$. Then, the energy of the electrons/positrons confined in the SNR would evolve as

$$\epsilon_e(t) = \epsilon'_e \left( \frac{t'}{t} \right)^{2/5},$$

and therefore, the distribution function of confined electrons/positrons can be evaluated as

$$N_{e,conf}(\epsilon_e, t) = \int_{t_{inj}}^{t'_{sedov}} dt' Q_0(t') \epsilon_e^{-a} \left( \frac{t'}{t} \right)^{2/5(1-a)} \times \exp \left( -\frac{\epsilon_e(t'/t')^{2/5}}{\epsilon_{e, cut}} \right) \times \Theta \left( \epsilon_{esc}(t') - \epsilon_e \right) \left( \frac{t'}{t} \right)^{2/5}.$$

If the decreasing rate of $\epsilon_{esc}$ is faster than the adiabatic cooling rate, $-2/5 \epsilon_{esc}/t$, then a part of the confined electrons/positrons can escape the SNR shock. By using the same logic in deriving Equation (21) of Ptuskin & Zirakashvili (2005) in the case of expanding media, we can evaluate the spectrum of such particles as

$$\dot{N}_{e,esc,2}(\epsilon_e, t) = -\delta(\epsilon_e - \epsilon_{esc}(t)) \left( \frac{d\epsilon_{esc}}{dt} + \frac{2\epsilon_e}{St} \right) N_{e,conf}(\epsilon_e, t).$$

Hereafter, we consider the spectrum of the escaping electrons'/positrons' number luminosity per energy as the sum of the above two components:

$$\dot{N}_{e,esc}(\epsilon_e) = \dot{N}_{e,esc,1}(\epsilon_e) + \dot{N}_{e,esc,2}(\epsilon_e).$$

We neglect the radiative energy loss of electrons/positrons during the confinement for simplicity. As we have shown in Equation (17), the electron flux of the second component $\dot{N}_{e,esc,2}(\epsilon_e, t)$ is determined by the difference between the decline rate of the escape energy $\dot{\epsilon}_{esc}$ and the energy loss rate of electrons/positrons. In the cases shown in this study, the decline rate of the escape energy is $-\alpha \epsilon_e / t \sim 3 \times 10^{-9} (\epsilon_e / \text{1 TeV}) (t / \text{10^4 yr})^{-1} \text{ GeV s}^{-1}$ ($\alpha \approx 1-2.6$, depending on the model), while the adiabatic cooling rate and the radiative cooling rate are $1.2 \times 10^{-9} (\epsilon_e / \text{1 TeV}) (t / \text{10^4 yr})^{-1} \text{ GeV s}^{-1}$ and $b \epsilon_e^2 \sim 10^{-10} (\epsilon_e / \text{1 TeV})^2 \text{ GeV s}^{-1}$, respectively, where for the latter we take the cooling rate for the interstellar space (see Section 2). Therefore, even if we take into account radiative cooling, the flux of the electrons/positrons which have once been confined in the SNR does not change its order from our calculation. Moreover, in the interstellar space the diffusion timescale for TeV electrons can be estimated as

$$t_{diff} \sim \frac{r^2}{4D(\epsilon_e)} \sim 1.4 \times 10^4 \text{ yr} \left( \frac{\epsilon_e}{3 \text{ TeV}} \right)^{-1/3} \left( \frac{r}{300 \text{ pc}} \right)^2,$$

and therefore the energy loss of TeV electrons during the propagation is at most $\Delta \epsilon_{e} / \epsilon_{e} \sim 1 - (1 + b_{diff} \epsilon_{e})^{-1} \sim 10\%$. Then we can say that in this energy range both the energy losses in the synchrotron emission may be faster than that due to the adiabatic expansion of the SNR, and even than that due to the decline rate of the escape energy. In such a case, the confined electrons/positrons cannot escape the SNR later and only the first component $\dot{N}_{e,esc,1}$ would be emitted and observed at the Earth. Anyway, as either the strength of the magnetic field in the PWN/SNR or its time evolution is generally uncertain, it is difficult to estimate the radiative cooling rate with a moderate strength of the magnetic field in a reliable way. In the following, we investigate only the case where the radiative energy loss is not significant.

4. OBSERVED ELECTRON SPECTRUM IN THE ESCAPE SCENARIO

Now that we have the time evolution of the escaping CR particle flux from the source, we can obtain the observed electron spectrum by solving the propagation of CR electrons/positrons with the diffusion equation shown in Equation (3). Once we know the Green’s function of this equation with respect to the time and position, $G(t, r, \epsilon_e; \tau)$, we can obtain the observed electron spectrum as

$$f(t, r, \epsilon_e) = \int_{t_0}^{t'} \dot{G}(t, r, \epsilon_e; \tau) d\tau,$$

where $t_0$ is the time when the particle injection has started, which is assumed to be equal to $t_{sedov}$ in the following discussions.

The mathematical description of $G(t, r, \epsilon_e; \tau)$ was derived by Atoyan et al. (1995),

$$G(t, r, \epsilon_e; t_0) = \frac{\dot{N}_{e,esc}(\epsilon_e, t_0) P(\epsilon_e)}{\pi^{3/2} \beta_{diff}(\epsilon_e,t_0)} \exp \left( -\frac{r^2}{\beta_{diff}(\epsilon_e,t_0)^2} \right),$$

where $\epsilon_{e,0}$ is the energy of the electrons/positrons at the time $t_0$ and which are cooled down to $\epsilon_e$ at the time $t$, and $\beta_{diff}$ is the
an index of

We adopt the background model of an exponentially cutoff power law with a source at 3.0 and a cutoff at 1.5 TeV, which is similar to that shown in Aharonian et al. (2008) and reproduces the data in ~10 GeV–1 TeV well, and we show the spectrum including this background by thick lines. We assume that a source at $r = 290$ pc from the Earth produces $e^\pm$ pairs with total energy $E_\nu = E_e = 0.5 \times 10^{8}$ erg, duration $t_0 = 10^{4}$ yr, spectral index $\alpha = 2.0$, and the high-energy break $E_{\nu, \text{cut}} = 10$ TeV.

A diffusion length given by

$$d_{\text{diff}} = 2 \left[ \int_{E_\nu}^{E_{\nu, \text{cut}}} \frac{D(x)dx}{P(x)} \right]^{-1/2},$$

as shown in Equations (10) and (11) in Atoyan et al. (1995).

In deriving the energy loss rate $P(\varepsilon_e)$, we use the formulation shown by Moderski et al. (2005),

$$P(\varepsilon_e) = \frac{4\pi\Gamma^2}{3m_e^2\varepsilon_e^3} \left( \frac{B^2}{8\pi} + \int d\varepsilon_\gamma u_{\text{tot}}(\varepsilon_\gamma) f_{\text{KN}} \left( \frac{4\varepsilon_e \varepsilon_\gamma}{m_e^2 c^4} \right) \right),$$

where $\sigma_T$ is the Thomson cross section, $u_{\text{tot}}(\varepsilon_\gamma)$ is the energy density of interstellar photons with the energy between $\varepsilon_e$ and $\varepsilon_\gamma + d\varepsilon_\gamma$ (including cosmic microwave background, starlight, and dust emission; Porter et al. 2008), and $B$ is the interstellar magnetic field which we here set as 1 $\mu$G. Here the function $f_{\text{KN}}(x)$ is the correction factor to include the Klein–Nishina (KN) effect. According to Moderski et al. (2005), this function can be expressed as

$$f_{\text{KN}}(\delta) = \frac{9g(\tilde{b})}{\tilde{b}^3},$$

where $\tilde{b} = 4\varepsilon_e \varepsilon_\gamma / (m_e c^2)^2$,

$$g(\tilde{b}) = \left( \frac{1}{2} \tilde{b} + 6 + \frac{6}{\tilde{b}} \right) \ln(1 + \tilde{b})$$

$$- \left( \frac{11}{12} \tilde{b}^3 + 6\tilde{b}^2 + 9\tilde{b} + 4 \right) \frac{1}{(1 + \tilde{b})^2} - 2 + 2 \text{Li}_2(-\tilde{b}),$$

and the function $\text{Li}_2(z)$ is the dilogarithm

$$\text{Li}_2(z) = \int_1^0 \frac{\ln(1 - t)dt}{t}. \quad (26)$$

According to recent experiments, especially HESS (Aharonian et al. 2008), the background CR electron/positron flux seems to have a high energy drop of around a few TeV. This drop is quite naturally explained in the context of the astrophysical origin of CR electrons/positrons because the number of sources contributing to the TeV energy band is quite small according to the birth rate of SNe/pulsars in the vicinity of the Earth (Kobayashi et al. 2004; Kawanaka et al. 2010). In fact, since the pulsars which contribute to the electron flux at the energy $\varepsilon_e$ should be younger than the cooling time of electrons/positrons $t_{\text{cool}} \sim 1/(\varepsilon_e)$ and should be located closer to the Earth than the diffusion length $d_{\text{diff}} \sim 2\sqrt{R(\varepsilon_e) t_{\text{cool}}}$, the number of pulsars contributing to $\geq$TeV band should be as small as

$$N_{\text{PSR}}(\varepsilon_e) \sim 6 \left( \frac{\varepsilon_e}{\text{TeV}} \right)^{-5/3} \left( \frac{R}{0.7 \times 10^{-5} \text{ yr}^{-1} \text{ kpc}^{-2}} \right). \quad (27)$$

where $R$ is the local pulsar birth rate per unit surface area of our Galaxy. If we can separate the contribution of a single young source from the observed electron spectrum, we can get the information of the CR injection into the ISM from that source. For this reason, we especially pay attention to the TeV spectral features of CR electrons from a pulsar in the following.

In Figures 3 and 4, we show the time evolutions of the CR electron spectrum from a nearby pulsar according to the models of the escape energy $E_{\text{esc}}(t)$ adopted in the previous section (see also Figure 2). It is clear that there exists a low-energy cutoff in each spectrum corresponding to the value of $E_{\text{esc}}(t)$ at that time. The spectral shapes generally depend on other parameters such as the high-energy break of the intrinsic electron spectrum, the spectral index, the duration of electron/positron injection from a pulsar, and the total energy of CR electrons/positrons. However, the sharp cutoff feature in the low-energy side of the spectrum is almost independent of these properties. In Figure 3, we can see that the low-energy cutoff of each spectrum is slightly broadened compared with that in Figure 4. This is because the model adopted in this figure assumes that $E_{\text{esc}}(t)$ decreases more rapidly than in the case of Figure 4 and so the CR electrons/positrons in the broader energy range can reach the observer, while in the case of Figure 4, where $E_{\text{esc}}(t)$ decreases slowly, the low-energy cutoff becomes very narrow. In either case the drop-off in the low-energy side of the spectrum is so steep that one should assume the intrinsic spectral index to be as hard

Figure 3. Electron spectra from a single pulsar surrounded by an SNR with different ages: $3 \times 10^3$ (dotted line), $5 \times 10^3$ (dashed line), $1 \times 10^4$ (solid line), and $2 \times 10^4$ yr (dot-dashed line). As for the model of the escape threshold energy $E_{\text{esc}}(t)$ we adopt the results by Gabici et al. (2009; see Figure 2). We adopt the background model of an exponentially cutoff power law with an index of $-3.0$ and a cutoff at 1.5 TeV, which is similar to that shown in Aharonian et al. (2008) and reproduces the data in ~10 GeV–1 TeV well, and we show the spectrum including this background by thick lines. We assume that a source at $r = 290$ pc from the Earth produces $e^\pm$ pairs with total energy $E_\nu = E_e = 0.5 \times 10^8$ erg, duration $t_0 = 10^4$ yr, spectral index $\alpha = 2.0$, and the high-energy break $E_{\nu, \text{cut}} = 10$ TeV.

as $\alpha \lesssim 0$–1 if we neglect the energy-dependent CR escape effects.

The CR electron spectrum with age and distance similar to the Vela pulsar ($t_{\text{age}} \approx 10^4$ yr, $r \approx 290$ pc), which is thought to be surrounded by the SNR (Aschenbach et al. 1995), is shown in Figure 5. Here we show the spectrum with the escape model of Ptuskin & Zirakashvili (2005) as well as the spectrum without the CR confinement in the SNR. In addition, the electron flux which has not been confined in the SNR (i.e., $N_{e,\text{esc},1}$) and that which has been once confined and later escaped ($N_{e,\text{esc},2}$) are shown. We can see that the latter component dominates the flux around the low-energy cutoff. In this case, we can detect the electron flux from the Vela pulsar having such a sharp spectral cutoff with near future missions such as CALET (we assume the geometrical factor $S\Omega$ times the observation time $T \approx 5$ yr as ~220 m$^2$ sr days) because the assumed electron/positron flux is sufficiently large and the low-energy cutoff comes beyond the high energy drop of the background flux inferred by HESS (Aharonian et al. 2009). If such a sharp cutoff feature is confirmed, that would be a strong evidence of the energy-dependent escape of CR particles from the acceleration site. As we mentioned in the previous section, the second component $N_{e,\text{esc},2}$ would not be observed if the magnetic field in the PWN is strong and the electrons/positrons once confined in the PWN/SNR lose their energy too rapidly to escape the SNR later. However, the first component $N_{e,\text{esc},1}$ also has a sharp cutoff in the low-energy side of its spectrum, and so even if in this case it is still possible to prove CR escape from an SNR through the electron spectrum. If the threshold energy $\epsilon_{\text{esc}}(t)$ at that time is smaller than a few TeV, then the cutoff feature would be hidden by the background flux. In fact, assuming the phenomenological model of $\epsilon_{\text{esc}}(t)$ adopted by Gabici et al. (2009) and Ohira et al. (2010), the low-energy end of the spectrum from the Vela pulsar would be buried in the background flux because the escape energy at the age of the Vela SNR ($\sim 10^4$ yr) becomes smaller than ~few TeV, and so the cutoff feature due to the energy-dependent escape of CR electrons/positrons may not be resolved.

As we mentioned in Section 1, CR escape from a source (i.e., SNR) seems to be an important process for the observed CR spectrum below the knee ($\sim 10^{15.5}$ eV) and the broken power-law gamma-ray spectra observed from SNRs interacting with molecular clouds. As for the spectrum of CR protons and nuclei we can only see the superposed flux from multiple CR sources with different ages, and so it is impossible to see the direct evidence of energy-dependent CR escape from a single CR source. On the other hand, in the ~1–10 TeV band of the CR electron spectrum we may be able to get the spectrum from a single source, and then we can expect the sharp low-energy cutoff showing the boundary between runaway CR electrons/positrons and confined CRs whose energies are not high enough to escape from the SNR shock. Therefore, this cutoff can be the first direct evidence that energy-dependent CR escape really occurs at the source of those CR electrons/positrons.

5. SUMMARY AND DISCUSSIONS

In this paper we show the possibility of obtaining evidence of energy-dependent CR escape from the SNR shock by observing the TeV CR electron spectrum. The escape of CR particles is the fundamental process in emitting CR particles accelerated at the SNR shock, and the history of the escape energy $\epsilon_{\text{esc}}(t)$, which is the threshold energy for accelerated particles not to be confined but to escape the shock into the ISM, is essential in determining the observed CR spectrum. Although there are some indirect suggestions to this scenario from recent gamma-ray observations of SNRs interacting with molecular clouds, we have not verified the energy-dependent CR escape model of SNRs directly from these observations.

In order to see the history of CR injections from SNRs, we focus on the lepton component of CRs. In the energy band larger than ~TeV, it is expected that the electron/positron flux from a few nearby young astrophysical sources (e.g., the Vela pulsar) can be observed; then, we will be able to get the information about the intrinsic CR spectrum from a single source at a certain time, which has not been well understood because the observed nuclear CR spectrum consists of the contributions from multiple sources and it is impossible to resolve the spectrum from a single source. Especially if a nearby young pulsar embedded in an SNR emits sufficiently large flux of CR electrons/positrons, they are injected into the SNR shock and only the electrons/positrons with energy larger than $\epsilon_{\text{esc}}(t)$ can go through the SNR and propagate into the ISM. As a result, the observed electron spectrum from that pulsar may have the low-energy cutoff corresponding to the escape energy $\epsilon_{\text{esc}}(t)$ at the observation time.

In order to detect such a spectral feature, the low-energy cutoff (i.e., $\epsilon_{\text{esc}}(t)$ at the observation time) should be above $\geq 1$–10 TeV because otherwise the cutoff would be buried in the background flux and would be hard to resolve.

The possibility that there is such a low-energy cutoff in TeV electron spectrum has first been pointed out by this study, and taking into account the variation of the CR escape history from the SNR and/or the age of the pulsar, we can predict a variety of spectral shapes that have not been considered in the context of astrophysical sources. For example, if the high-energy cutoff of the spectrum, which is determined by the intrinsic cutoff energy at the pulsar and the radiative energy loss of electrons/positrons during their propagation, is nearly equal to the low-energy cutoff determined by the escape from the SNR, the resulting spectrum would have a narrow-line-like shape and it would be similar to that expected from the annihilation of dark matter particles. Whether the observed CR electron spectrum
