Long-Term Patency Rate of Radial Artery Conduits in Chinese Patients Undergoing Off-Pump Coronary Artery Bypass Grafting

Qiang Ji,1 MD, Kai Song,2 MD, JinQiang Shen,1 YuLin Wang,1 MD, Ye Yang,1 MD, WenJun Ding,1 MD, LiMin Xia,1 MD and ChunSheng Wang,2 MD

Summary

Consensus has yet to emerge among experts as to whether the radial artery (RA) conduit was superior to the saphenous vein (SV) graft for coronary artery bypass grafting (CABG) in terms of long-term patency. This study aimed to evaluate long-term patency of the RA conduit compared to the SV conduit for off-pump CABG, and to screen the independent predictors of long-term RA graft failure.

Patients < 80 years of age with graftable triple-vessel disease undergoing non-emergent, primary, isolated off-pump CABG, using both the RA and the SV conduits, were reviewed. Graft patency, all-cause mortality and repeat revascularization were followed-up. The independent predictors of long-term RA graft failure were identified.

A total of 296 out of 320 eligible patients (42 females, 61.3 ± 9.9 years old) received follow-up with an observed period of 93.4 ± 16.5 months. All-cause mortality was 14.5%, and repeat revascularization was conducted on 6 RA grafts and 9 SV grafts. Superior patency of the RA grafts compared to the SV grafts was observed (84.4% versus 78.5%, \( P = 0.035 \)). Independent predictors of long-term RA graft failure included proximal stenosis of target right coronaries < 90% (OR = 2.35, 95%CI 1.41-5.82) and diabetes mellitus (OR = 1.66, 95%CI 1.17-4.26).

The RA graft had a superior long-term patency than the SV graft. Long-term patency of the RA graft may be poor in diabetics or in the case of proximal stenosis of target right coronary <90%. (Trial registration: ChiCTR-OCH-1200212)

Key words: Saphenous vein, Graft failure, Diabetics

As early as 1971, the “skeletonized” radial artery (RA) was applied as a conduit for coronary artery bypass grafting (CABG), benefiting from a larger inner diameter relative to other arterial grafts, easy harvesting, and a lower incidence of wound infection. However, the incidence of vasospasm and functional occlusion of the RA conduit was as high as 35%, resulting in a majority of cardiac surgeons abandoning the RA grafting for some years.1) Afterwards, RA graft re-patency following early vasospasm and functional occlusion was found, wakening cardiac surgeons’ interest in the RA grafting.2) Subsequently, the use of the RA as a bypass conduit for CABG was increasing.

Patency of the revascularization conduit was an essential predictor of long-standing survival following CABG surgery. Several previous reports supported the use of the RA conduit in preference to the saphenous vein (SV) graft,3-10 while other studies suggested the opposite.11-14 Ongoing doubt and debate remained regarding the efficacy of the RA as an aorta-coronary conduit, with few solid data regarding long-term patency. Also, consensus has yet to emerge among experts as to whether the RA conduit was superior long-term patency to the SV graft.

In this study, 320 patients < 80 years of age undergoing non-emergent primary isolated off-pump CABG with the use of both RA and SV grafts were reviewed and followed-up, in order to evaluate the long-term patency of the RA conduits compared to the SV grafts, and to screen the independent predictors of long-term RA graft failure.

Methods

Inclusion criteria: Patients < 80 years of age with graftable triple-vessel disease and an estimated left ven...
tricular ejection fraction of more than 35% who received non-emergent, primary, isolated, off-pump CABG, who had both RA and SV grafts from January 2005 to December 2008 were eligible for this study. Patients with concomitant left ventricular aneurysm surgery, any concomitant acquired or congenital cardiac or aortic surgery, or concomitant malignancy were excluded. In addition, patients with hyperthyroidism, iodine contrast medium allergy, atrial fibrillation, and renal insufficiency may not be suitable candidates for coronary computer tomography (CT) angiographic examination, and thus, were not involved in the final analysis.

Study protocol: This study protocol was approved by the ethics committee of Zhongshan Hospital Fudan University and was consistent with the Declaration of Helsinki (Trial registration: ChiCTR-OCH-1200212). All included patients were followed-up for graft patency, all-cause mortality and repeat revascularization.\(^{15}\) Graft patency was determined by non-invasive coronary CT angiography with a 64-slice, dual-source CT (iCT 64, Philips Healthcare, Amsterdam, Netherlands). If patients developed symptoms or doubtful symptoms of coronary heart disease during follow-up, non-invasive coronary CT angiography or invasive coronary angiography should be performed at the time; on the other hand, asymptomatic patients received non-invasive coronary CT angiography at the 13th month following surgery and then once every two years. Conduits were evaluated for failure (≥50% lumen diameter reduction and/or reducing the caliber of distal anastomosis to ≥50% of the grafted coronary artery). A sequential conduit was divided into multiple segments according to the number of distal anastomoses. Each angiogram was independently adjudicated in a blinded fashion by two committee members, with a third review in the case of disagreement of the primary or secondary outcome. Also, in-hospital mortality, major postoperative morbidity,\(^{56}\) and hands as well as arms complications potentially related to harvest of the RA conduits were recorded.

All patient follow-ups were divided into two groups: the failure group (RA graft failure) and the patency group (RA graft patency). Baseline characteristics, in-hospital and follow-up outcomes were compared between the two groups.

Surgical procedures and postoperative management: The pedicled RA was harvested from the antecubital fossa to the wrist in the arm, from the non-dominant arm, with the use of an electrocautery in an open fashion. After harvesting, the RA was rinsed and kept in a nitroglycerin and papaverin solution. The SV and the left internal mammary artery (LIMA) were harvested by the standard method. The target vessels for the RA conduits included the right coronary territory, the circumflex territory, the diagonal artery, and the left anterior descending coronary artery (LAD). The RA was bypass grafted to either the right or the left coronary territory, and the SV was used for the other territory besides the LAD. The target vessels for the RA conduits or the SV conduits had >70% stenosis, were >1.5 mm in diameter, and were deemed to be of acceptable quality according to visual assessment of the preoperative coronary angiogram by the operating surgeon. The detailed off-pump CABG procedure was referred to the related literature.\(^{17}\) Surgeons were at liberty to choose sequential or separate RA or SV grafting for each case.

Subcutaneous injection of low molecular weight heparin within 6h following surgery was performed routinely, except for patients undergoing re-operation for bleeding. Statin medication, aspirin, and clopidogrel were routinely prescribed to all patients starting from postoperative day 1 or 2. Statin medication and aspirin were continued indefinitely, whereas clopidogrel was discontinued after one year. Also, patients received intravenous calcium channel blockers infusion at the beginning of the operation and continued for one day with concomitant oral calcium channel blockers overlap. After 24 hours, the intravenous infusion was discontinued, and the oral regimen maintained for one year.

Statistical analysis: Peri-operative data were obtained from our institutional database and reviewed using a standard data collection form. Follow-up data were obtained by telephone and clinic visit. Data collection was performed by trained staff (two people). The trained staff, however, did not know the purpose of the study.

Normally distributed continuous variables were expressed as the mean ± standard deviation and were compared between groups using the Student’s t-test. Non-normally distributed continuous variables were expressed as median and compared between groups with the Wilcoxon rank sum test. Categorical variables were expressed as frequency distributions and single percentages and were compared between groups using χ² test or Fisher’s exact test, when appropriate. Cumulative graft patency was analyzed by the Kaplan-Meier method with the log-rank test for a comparison between the RA and the SV conduits. The independent predictors of long-term graft failure were identified using univariate analysis and then multivariate logistic regression with the backward method. A value of two-sided P less than 0.05 was considered statistically significant. Statistical analysis was performed with SPSS statistical package version 22.0 (SPSS Inc., Chicago, IL, USA).

Results

Study population: A total of 358 patients meeting the inclusion criteria were included in this study. Thirty-eight patients were excluded (concomitant left ventricular aneurysm surgery in 5, concomitant malignancy in 5, concomitant hyperthyroidism in 1, concomitant atrial fibrillation in 7, and chronic renal dysfunction in 20), and finally 320 patients (42 females, 61.3 ± 9.9 years old) were analyzed. Baseline characteristics are shown in Table I. The number of distal anastomoses ranged from 3 to 6 (mean 3.8 per patient). Note that 9 patients (2.8%) received LAD revascularization using RA conduits; 91.3% of patients received separate RA grafting, leaving 28 patients undergoing sequential RA grafting (from aorta to the diagonal and then to the circumflex territory). Further, 38.9% of RA conduits and 43.1% of SV conduits were grafted target coronary arteries with proximal stenosis <90% (P = 0.260).

Clinical outcomes: In-hospital clinical outcomes are presented in Table II. In-hospital mortality was 1.6%. The

COPD indicates chronic obstructive pulmonary disease; MI, myocardial infarction; PCI, percutaneous cardiac intervention; LVEF, left ventricular ejection fraction; LVEDD, left ventricular endo-diastolic diameter; CABG, coronary artery bypass grafting; CPB, cardiopulmonary bypass; LM, left main coronary artery; LIMA, left internal mammary artery; RA, radial artery; LAD, left anterior descending coronary artery; and SVG, saphenous vein graft. *Hepatic dysfunction was recognized on the basis of Child-Pugh scores. #Recent MI: evidence of MI within the last 30 days before surgery.
cause of death included cardiogenic death (2 cases), gastrointestinal hemorrhage (1), respiratory failure (1) and multiple organ failure caused by mediastinitis (1). One patient required readmission because of infection at the site where the RA was harvested. Thirty-one patients (9.7%) reported moderate-to-severe symptoms of thenar paresthesia or numbness at discharge, and this number had decreased to three patients (0.9%) within 12 months postoperatively. Six patients (1.9%) reported moderate-to-severe weakness of the hand at discharge, and this number had increased to three patients (0.9%) within 12 months postoperatively. No hand claudication or ischemia was observed.

A total of 296 patients (92.5%) received follow-up with an observed period of 93.4 ± 16.5 months. As shown in Table II, follow-up all-cause mortality was 14.5%. Four patients died within one year following surgery, and the causes of death included myocardial infarction (1 case), infection (1), gastrointestinal hemorrhage (1) and pericardial effusion (1). Another 14 patients died within 13 months to five years following surgery, and the causes of death included myocardial infarction (2), heart failure (3), infection (4), hepatic failure (1), gastrointestinal hemorrhage (1) and malignant tumor (3). Over five years after surgery, 25 patients died; the main causes of death were listed as follows: myocardial infarction (3), heart failure (4), cerebral hemorrhage (2), gastrointestinal hemorrhage (1), infection (5), renal failure (1), malignant tumor (6), high falling injury (1) and traffic accident (2). Additionally, 16 patients underwent repeat revascularization, with the incidence of 5.4%. Only 1 patient received repeat on-pump CABG surgery due to complete occlusion of the RA graft from the aorta to the LAD. Intervention was conducted on 4 separate RA grafts (grafting to the right coronary territory in 3 and to the diagonal artery in 1) and 1 sequential RA graft between diagonal and obtuse marginal artery.

**Graft patency:** A total of 296 patients, including 320 RA grafts or segments (272 separate and 24 sequential grafts), 525 SV grafts or segments (67 separate and 229 sequential grafts) and 292 LIMA grafts, received non-invasive coronary CT angiography during follow-up. Table III lists the long-term patency rate of grafts or segments. The RA grafts had a significantly higher patency rate as compared to the SV grafts (84.4% versus 78.5%, $P = 0.035$). Separate RA grafting to the right coronary territory with proximal native coronary stenosis ≥ 90% had a higher patency rate compared to <90% (87.8% versus 68.4%, $P = 0.004$). Separate or sequential RA grafting to the left coronary territory had a higher patency rate than separate RA grafting to the right coronary territory with proximal native coronary stenosis < 90% (87.2% versus 68.4%, $P = 0.009$; 89.6% versus 68.4%, $P = 0.003$, respectively). No significant difference was found in terms of the RA graft patency between concomitant sequential SV grafting and concomitant separate SV grafting (84.3% versus 84.6%, $P = 0.940$). Also, the RA grafts had better cumulative patency rate than did the SV grafts in the Kaplan-Meier curve ($\chi^2 = 6.515$, log-rank $P = 0.011$) (Figure).

**Risk factors for graft failure:** Forty-eight patients who developed RA graft failure during follow-up were entered into the failure group, and the remaining 248 patients into the patency group. As presented in Table IV, significant differences were found between the two groups in gender (female versus male), recent smoking, concomitant with diabetes mellitus, the extent of proximal stenosis of target right coronary territory (< 90% versus ≥ 90%), acute myocardial infarction associated with CABG, and requiring hemodialysis. No significant difference was found between the two groups in terms of the RA graft patency between concomitant sequential SV grafting and concomitant separate SV grafting (84.3% versus 84.6%, $P = 0.940$). Also, the RA grafts had better cumulative patency rate than did the SV grafts in the Kaplan-Meier curve ($\chi^2 = 6.515$, log-rank $P = 0.011$) (Figure). 

**Table II. Clinical Outcomes**

| Parameter                                      | Number of patients |
|------------------------------------------------|--------------------|
| In-hospital                                    |                    |

could not be related to proximal stenosis of target vessels. This study reported long-term RA graft patency of 84.4%, which was significantly higher than the SV graft. And results of this study showed that the RA graft had superior cumulative patency than did the SV graft. These results suggested that the RA graft was superior to the SV graft in terms of long-term patency. Several previous studies reported the mid- to long-term patency of the RA graft. Buxton and colleagues\textsuperscript{18} reported the RA graft received a similar five-year's patency with the SV graft in a prospective, randomized study. A multicenter clinical trial\textsuperscript{20} showed that the RA and the SV grafts received similar incidence of complete graft occlusion at one year (11%). Nevertheless, most previous reports supported the use of the RA conduit instead of the SV graft. Zacharias and colleagues\textsuperscript{20} evaluated the 6-year's clinical outcomes of propensity-matched patients undergoing LIMA-to-LAD with either an additional RA graft or SV graft as the second conduit, and showed a trend toward higher RA graft patency. Desai and colleagues\textsuperscript{21} in the first multicenter clinical trial (Radial Artery Patency Study) showed that the RA graft had a protective effect against occlusion

Table III. Graft Failure (Patency Rate) Determined by CT Angiography

| Grafts                          | Number of failure | Patency rate |
|---------------------------------|-------------------|--------------|
| LIMA grafts                     | 17 (275/292 = 94.2%) |
| RA grafts or segments           | 50 (270/320 = 84.4%) |
| Sequential RA segments          | 5 (43/48 = 89.6%) |
| Separate RA grafts              | 45 (227/272 = 83.4%) |
| Grafting to left coronaries      | 16 (109/125 = 87.2%) |
| Grafting to right coronaries     | 29 (118/147 = 80.3%) |
| < 90% proximal stenosis of target coronaries | 18 (39/57 = 68.4%) |
| ≥ 90% proximal stenosis of target coronaries | 11 (79/90 = 87.8%) |
| SV grafts or segments           | 113 (412/525 = 78.5%) |
| Separate SV segments            | 93 (365/458 = 79.7%) |
| Concomitant RA graft failure*    | 36 (193/229 = 84.3%) |
| Separate SV grafts              | 20 (47/67 = 70.1%) |
| Concomitant RA graft failure#    | 14 (77/91 = 84.6%) |

CT indicates computed tomography; LIMA, left internal mammary artery; RA, radial artery; and SV, saphenous vein. *Concomitant RA graft failure, RA graft failure in the case of patients undergoing concomitant sequential SV grafting; # Concomitant RA graft failure, RA graft failure in the case of patients undergoing concomitant separate SV grafting.
through comparing angiographic data of 440 RA grafts with 440 SV grafts for more than five years. The single-center Radial Artery Versus Saphenous Vein Patency trial (RSVP trial) reported that complete graft occlusion was markedly less frequent in the RA graft compared with the SV graft. Deb and colleagues updated Athanasiou’s review with results from the RAPS study and new data, and found that the RA graft, compared to the SV graft, was associated with reduced graft failure more than five years after isolated CABG surgery. These pieces of evidence were consistent with results of this study.

Another important finding was that proximal stenosis of target right coronary territory ≤ 90% and concomitant with diabetes mellitus were two independent predictors of long-term RA graft failure. Data from this study showed separate RA grafting to the right coronaries with proximal stenosis ≥ 90% compared to < 90% had a higher patency rate, and the risk of RA graft failure in patients with proximal stenosis of target right coronaries ≤ 90% was 2.35 times than that in patients with proximal stenosis of target right coronaries > 90%. suggesting that the more serious proximal stenosis of target right coronaries, the

Failure group indicates patients receiving radial artery graft failure during follow-up; patency group, patients receiving radial artery graft patency during follow-up; COPD, chronic obstructive pulmonary disease; MI, myocardial infarction; PCI, percutaneous coronary intervention; LV, left ventricle; LIMA, left internal mammary artery; RA, radial artery; and SVG, saphenous vein graft.
higher RA graft patency. Desai and colleagues \cite{21} reported that grafting to a vessel with proximal occlusion improved the RA patency. The single-center RSVP study \cite{5} also reported that graft patency was improved when the RA was directed to a more severely narrowed target vessel. A meta-analysis \cite{22} showed that patients with severe proximal stenosis may have better mid-term patency after the RA bypass grafting. This evidence was in line with results of this study. The reason may be related to blood flow competition between the RA graft and target coronaries.\cite{5,5,20,22} Certain characteristics of the RA, including the increased wall thickness and the density and organization of myocytes, may increase the propensity of this artery for spasm when there was decreased or competitive flow.\cite{23} Also, this study showed that diabetes mellitus was an independent predictor of RA graft failure. The reason of that may be that diabetes mellitus was responsible for acceleration and worsening of atherothrombosis.\cite{24} In addition, results of this study showed that, besides concomitant with diabetes mellitus, proximal stenosis for the target right coronary territory < 90% was an independent risk factor for long-term RA graft failure, whereas concomitant with dyslipidemia was an independent predictors of long-term SV graft failure. Our results suggested that blood flow competition played an important role in the development of RA graft failure but had no obvious effect on the development of SV graft failure; and hyperlipidemia, the major risk factor of causing atherosclerosis,\cite{25} had significant effects on the progress of SV graft failure. The reason for this difference may be related to the different physiological characteristics between the muscular artery and the vein.

It was also important to keep in mind that the RA bypass grafting was not indicated for all patients. Patients with a positive Allen’s test, a history of Raynaud’s syndrome or vasculitis, or inadequate ulnar compensation, as determined by non-invasive Doppler vascular ultrasound, may not be suitable candidates for the RA bypass grafting. Patients with widespread atherosclerotic coronary anastomosis regions and/or widespread atherosclerotic distal regions of the target coronaries were not suitable candidates for the RA grafting. Also, the ideal target vessel for the RA grafting may be a reasonably sized ( > 1.5 mm) coronary artery with preferable ≥ 90% proximal native coronary stenosis in non-diabetic patients. The decision about the use of the RA graft should be tailored individually in order to achieve the greatest clinical benefit for patients.

The RA patency after off-pump CABG did not translate into the RA patency following on-pump CABG. Off-pump coronary bypass surgery, compared to on-pump, may have an adverse effect on anastomotic patency, resulting in potentially inferior RA patency after off-pump CABG. However, we did not have enough data to identify the RA patency after on-pump CABG. Despite over 1000 cases of CABG procedure annually in our institution, more than 95% of isolated CABG procedure were conducted without cardiopulmonary bypass, and few patients received on-pump RA grafting. Whether there were differences in the RA patency between off-pump and on-pump CABG needed prospective and multicenter studies involving large sample size. In particular, it should be included data from the major medical centers in which off-pump CABG was the predominant method of surgical revascularization.

Note that the prevalence rate of recent smoking was up to 55.0% in this cohort, with far above 30% in the Western countries reports.\cite{27,28} Although the public gradually raised awareness of the dangers of smoking, and Chinese government attached great importance to tobacco control, the prevalence rate of smoking in China remains unacceptably high in the current era.\cite{29} So far, China has become the largest tobacco producer and consumer in the world, with more than 300 million smokers.\cite{29} This study suggested that tobacco control have not advanced very far, and more measures were needed.

There are several limitations of this study. First, it was a single-center study with a limited sample size. A final determination of effect would need a multicenter study involving a larger sample size. Second, non-invasive coronary CT angiography was used to determine the patency of the RA and the SV grafts. Non-invasive coronary CT angiography may be less accurate for assessing graft patency than invasive coronary angiography, but it is the more favorable choice of patients who schedule for an examination of graft patency.\cite{30} Third, angiographic data were limited, and we could not ascertain the inner diameter of the RA, the SV, and target coronaries. Finally, the follow-up duration in this study was relatively short (eight years or so), which may lead to the underestimation of net benefit of the RA grafting in comparison with the SV grafting.

### Conclusions

The RA graft had a superior long-term patency than did the SV graft. Long-term patency of the RA graft may

### Table V. Independent Predictors of Long-Term RA Graft Failure

| Variable                                   | OR    | 95% CI          | P value |
