Abstract Information about growth of kidney structures in early life is limited. In a population-based prospective cohort study, from foetal life onwards, we constructed reference curves for kidney growth from the third trimester of pregnancy until early childhood, using data from 1,158 healthy children. Kidney size, defined as length, width, depth and volume, was measured in the third trimester of pregnancy and at the postnatal ages of 6 months and 24 months. Analyses were based on more than 2,500 kidney measurements. In the third trimester of pregnancy and at 6 months of age all kidney measurements were larger in boys than in girls. At 24 months of age, these gender differences were only significant for left kidney structures and right kidney length. Both groups showed trends towards smaller left kidney measurements than right kidney measurements at all ages. Gender-specific reference curves based on post-conceptional and postnatal ages were constructed for left and right kidney length, width, depth and volume. We concluded that kidney size is influenced by age and gender. Left kidney size tended to be smaller than right kidney size, except for kidney length. The reference curves can be used for assessing kidney structures by ultrasound in foetal life and early childhood.

Introduction

Assessment of kidney size in children is important for clinical and epidemiological studies. Abnormal early kidney development may have perinatal and neonatal consequences [1]. Smaller foetal kidney size has also been suggested to be related to hypertension and renal disease in adulthood [2, 3]. Recently, we showed in the same cohort that small kidney size in foetal life tends to persist in early childhood. Furthermore, maternal anthropometric characteristics, foetal biometric data and blood flow patterns were associated with kidney size in childhood. Higher growth rates in early childhood were positively associated with combined kidney volume [4]. These results suggest that variations in foetal and early postnatal exposure and growth might have persistent consequences for kidney size. Kidney size can be measured non-invasively and efficiently with ultrasound. Few studies have published reference ranges for kidney size in healthy children during foetal and neonatal life [5, 6]. One study showed reference data on postnatal kidney growth from birth to 18 months of age [7]. Previous studies were based on the characteristics of postnatal kidney growth and focused mostly on kidney volume in relation to weight, height or body surface area. Recently, new reference centiles were generated to assess kidney size in children with ‘single kidneys’ to identify those patients with unfavourable courses and relevant single kidney growth impairment [8]. Currently, there are no studies that have evaluated normal kidney growth from late foetal life to early childhood. This perinatal period may be of importance in the identification of abnormal kidney size and growth, with subsequent short-term and long-term clinical consequences [9, 10].

Therefore, the aim of this study was to construct reference curves for kidney structures including kidney length, width, depth and volume in children from the third trimester of pregnancy until the postnatal age of 24 months in a population-based cohort.

Methods

Study design

This study was embedded in the Generation R Study, a population-based prospective cohort study from foetal life until young adulthood in Rotterdam, The Netherlands [11, 12]. Detailed assessments of foetal and postnatal growth and development were conducted in a subgroup of 1,232 mothers and their children [11, 12]. In this subgroup foetal kidney ultrasounds were performed in the third trimester of pregnancy (gestational age 30 weeks) and postnatal kidney ultrasounds were performed at the ages of 6 months and 24 months. The study was approved by the Medical Ethics Committee of the Erasmus MC, Rotterdam. Written informed consent was obtained from all participants.

Population for analysis

In total, 1,232 women were enrolled in the Focus cohort. The analysis was limited to singleton live-born infants (n=1,215) whose mothers had participated in the third trimester measurements. Twin pregnancies (n=15) and pregnancies leading to perinatal death (n=2) were excluded from the analysis. Kidney ultrasounds were successfully performed in 95% (n=1,158) of these subjects. Of the initial 1,215 singleton live-born infants, 74% (n=901) and 70% (n=856) underwent postnatal assessment at the ages of 6 months and 24 months, respectively. Kidney ultrasounds were successfully performed in 83% (n=747) and 80% (n=683) of these infants, respectively. Missing values were mainly due to the infants crying or to the unavailability of equipment or radiographer. Infants who had undergone a postnatal kidney ultrasound at the ages of 6 months and 24 months did not differ from the postnatal non-responders in foetal and birth characteristics. There were no kidney or ureterovesical anomalies other than mild pyelectasis over 10 mm (n=3) in our study population. In total, analyses were based on more than 2,500 kidney measurements. The numbers of kidney growth measurements available for the analyses are shown in Table 1.

Ultrasound measurements

Gestational age was established by foetal ultrasound. Crown–rump length was used for pregnancy dating until a gestational age of 12 weeks and 5 days (crown–rump length smaller than 65 mm), and biparietal diameter was used for pregnancy dating thereafter (gestational age from 12 weeks and 5 days onwards, biparietal diameter larger than 23 mm) [13].

Foetal left and right kidneys were measured in the third trimester of pregnancy with an ATL-Philips HDI 5000 instrument (Seattle, WA, USA) equipped with a 2.0–5.0 MHz curved array transducer. In a sagittal plane the maximum longitudinal kidney length was measured, with the calipers placed on the outer edges of the caudal and cranial sides. Antero-posterior (kidney width) and transverse (kidney depth) diameters were measured perpendicular to each other, outer to outer, in an axial plane [14]. Values of maximum bipolar kidney length, width and depth were obtained from both the left and right kidneys. Kidney width and depth were measured at the level of the kidney hilum [14, 15]. The images were magnified to ensure optimal measurements [14]. Foetal growth characteristics (head circumference, abdomen circumference, femur length) were measures at the same visit, and foetal weight was estimated [13].
Postnatally, two-dimensional ultrasounds of the kidneys were performed in children at the ages of 6 months and 24 months. The examination was carried out in a quiet room with the child quietly awake in a supine position. This position was standardised to prevent differences resulting from position [14, 15]. Mean length, width and depth were calculated as the average of three measurements and used for data analysis. Foetal and postnatal kidney volumes were both calculated in cubic centimetres using the equation of an ellipsoid: volume cm$^3$ = $0.523 \times \frac{\text{mean length} \times \text{mean width} \times \text{mean depth}}{3}$ [15, 16]. The infants’ anthropometric parameters, including weight and length, were all measured at the ages of 1.5 months, 6 months and 24 months. Date of birth, birth weight and gender were obtained from midwife and hospital registers.

For the foetal ultrasound measurements, intra- and inter-observer studies showed the intraclass correlation coefficient (ICC) to be higher than 0.98 and the corresponding coefficients of variation (CV) to be lower than 6%. Bland and Altman plots to test agreement of measurements demonstrated 95% limits of agreement to be within 10% difference from the mean of measurements, indicating good reproducibility [17]. For the postnatal ultrasound measurements, the intra-observer ICCs ranged from 0.93 (left and

right renal widths and right renal thickness) to 0.99 (left renal length), and interobserver ICCs ranged from 0.64 (right renal thickness) to 0.90 (right renal length). Limits of agreement in the Bland and Altman plots ranged from −8.0% to 9.2% (intra-observer left renal width) to the widest limit from −18.0% to 19.2% (interobserver left renal length) [18].

Data analysis

Differences in foetal and postnatal characteristics between boys and girls were assessed by $t$-tests and chi-square tests for independent samples. Differences between left and right kidney were tested with paired-samples $t$-tests.

Fig. 1 Reference growth curves of right and left kidney length, width, depth and volume in boys and girls, according to post-conceptional age. a Left kidney length, b right kidney length, c left kidney width, d right kidney width, e left kidney depth, f right kidney depth, g left kidney volume, h right kidney volume. Gender-differentiated growth curves for left and right kidney length, width, depth and volume measurements in relation to post-conceptional age with 3rd and 97th fitted centiles. The *straight lines* represent boys and the *dotted lines* represent girls.
Fig. 1 (continued)
Data were analysed as recommended by Altman and Chitty [19] and Royston and Altman [20]. For the reference curves for kidney growth, post-conceptional age was plotted against kidney length, width, depth and volume. From the original data, measurements of more than two standard deviations (SDs) from the regression line, fitted on our data, were considered to be outliers (n=10) and were therefore removed. They were probably a result of measurement error or a data entry error. The best-fitting curves were determined by second-degree fractional polynomials [21]. We fitted the curves, using repeated measurement analyses and taking into account the dependency in the data by specifying a constant covariance between measurements of the same subject [20, 22]. The best-fitting fractional polynomial curves were chosen by our comparing the deviances, by Akaike's information criterion, and by our visually checking the goodness of fit. Next, regression lines were fitted for the dependency of the residual SD on conceptional age [23]. Subsequently, we plotted the SD scores against conceptional age to assess the correctness of the model.

Finally, centiles were derived and the curves were plotted on the data. The median age of 2-year-old children visiting the research centre was 25 months (95% range 23.6–28.3 months). Since only 34 children had undergone measurement beyond the postnatal age of 28 months (160 weeks after conception), the results are presented up to the postnatal age of 28 months. Reference curves for kidney growth were constructed for a post-conceptional age from 30 weeks to 160 weeks, corresponding to a gestational age of 30 weeks and a postnatal age of 28 months.

All statistical analyses were performed with the Statistical Package for the Social Sciences, version 15.0, for Windows (SPSS Inc, Chicago, IL, USA) and the Statistical Analysis System (SAS) for Windows, version 9.1.3.
Results

The percentage of boys was 52% (Table 2). The overall median age at the third trimester of pregnancy was 30 weeks of gestation (total range 27.1–35.1 weeks). The overall median age of the infants at their 6-month postnatal visit was 6.3 months (total range 5.1–11.0 months), and at their 24-month postnatal visit it was 25.1 months (total range 21.6–31.6 months). Head circumference at the third trimester and postnatal weight and length at the ages of 6 months and 24 months were larger in boys than in girls (all P values <0.001). No difference was found for gestational age at birth between boys and girls. In total, 15 children in our study group were born with a small size for gestational age (<2 standard deviation scores (SDS)), 18 children had a low birth weight (<2,500 g) and 23 children were born before term (gestational age <37 weeks). Table 3 shows that in the third trimester of pregnancy and at the age of 6 months all kidney measurements were larger in boys than in girls. At the age of 24 months, these gender differences were only significant for left kidney structures and right kidney length. Both groups showed trends towards smaller left kidney measurements than right kidney measurements at all ages (Table 4).

Reference curves for individual measurements of kidney growth and fitted centiles are given in Fig. 1. Formulae for growth reference curves describing the mean with the corresponding standard deviation are given in Table 5. Standard deviation increased linearly with gestational age.

Reference values for kidney length, width, depth and volume are given in the Appendix (Tables 1S–4S).

Discussion

We constructed gender-specific reference growth curves for kidney length, width, depth and volume using measurements from a large population-based prospective cohort study of healthy children followed from foetal life until early childhood. We observed differences in kidney structures between left and right kidneys and boys and girls.

The major strength of our study is its prospective design from foetal life and the size of the population-based cohort. Our reference curves were based on more than 2,500 kidney measurements. To our knowledge, no previous studies that focused on kidney size in early life were based on such large numbers. All foetal ultrasounds were carried out by two sonographers, and 86% of all postnatal ultrasounds were performed by one trained sonographer [24]. A limitation could be that in all children participating in the Generation R measurements at the ages of 6 months and 24 months, kidney measurements were successfully performed in 83% and 80% of these infants, respectively. Missing values were mainly due to the infants crying or to the unavailability of equipment or radiographer. Our results would have been biased if the subjects’ characteristics had differed between those included and those not included in the analyses. However, we observed no differences in

| Kidney measurement | Measurement | Regression equation |
|--------------------|-------------|---------------------|
| **Left kidney**    |             |                     |
| Length (mm)        | Mean        | 70.7392 + 48231 × (1/Age2) − 22290 × (1/Age2) × ln(Age) − 1.0112 × Gender |
|                    | SD          | 3.033 + 0.020 × Age |
| Width (mm)         | Mean        | 33.9989 + 2465.42 × (1/Age2) − 408.99 × (1/Age) − 0.6208 × Gender |
|                    | SD          | 2.577 + 0.004 × Age |

growth and foetal kidney characteristics between the subjects that had undergone postnatal kidney measurement and those that had not. Another limitation could be that the study was performed in a healthy population-based cohort study. The selection towards a healthy population in our cohort might lead to a limited generalisability to preterm children or to children that were small for gestational age at birth. These numbers were too small to be assessed in further detail.

In the third trimester of pregnancy and at the age of 6 months all kidney measurements were larger in boys than in girls. At the age of 24 months, these gender differences were only significant for left kidney structures and right kidney length. Several studies of healthy neonates and adults have also shown that male subjects have larger kidneys than those of female subjects [25, 26]. One explanation for this finding might be a growth-stimulating effect of androgens, or Y-chromosome-related genes. Another explanation could be that during foetal life testosterone levels are significantly higher in boys than in girls [27, 28].

Previously published data have shown conflicting results concerning differences between left and right kidney size. Some studies found no difference [29, 30], whereas others have suggested the left kidney to be larger [31, 32]. Most consistent findings have been reported for kidney length, for which the left kidney seems to be longer than the right [7, 25, 26, 31, 33]. We found that the left kidney was longer in both boys and girls at the postnatal ages of 6 months and 24 months. In foetal life we found no significant difference between left and right kidney length.

Kidney growth is fastest during foetal life and early infancy, and the rate of increase gradually slows through the remainder of the first year of life and finally stabilises [34]. In our study numbers and curves for the 3rd centiles showed decreasing kidney volume at older ages, from 140 weeks and onwards. The decreasing numbers are due to wider ranges, because of the low number of children with visits around 140 weeks and onwards. To deal with non-linear kidney growth, some sonographic standards, including means and standard deviations, for kidney size in relation to age have been published [34–36]. A few other studies created linear or non-linear polynomial regression equations for kidney size during the first year of life [29, 33]. One study created reference material for kidney size in healthy children beyond the neonatal period [7]. The authors only focused on kidney volume in relation to weight, height and body surface area and did not report data about prenatal kidney growth. To our knowledge, our study is the first to provide prospective longitudinal reference material for kidney size that covers the whole period from foetal life to infancy in a healthy population.

In conclusion, kidney size differed between boys and girls from the age of 30 weeks of pregnancy until 24 months of age. The left kidney tended to be smaller than the right kidney. At the age of 24 months, the differences in right kidney size between boys and girls were attenuated. Gender-differentiated reference growth curves for both left and right kidneys were constructed for kidney length, width, depth and volume. These reference curves may be of importance in the identification of abnormal kidney size and growth, with possible subsequent clinical consequences.

Acknowledgements The Generation R Study was conducted by the Erasmus Medical Center in close collaboration with the School of Law and the Faculty of Social Sciences at the Erasmus University, Rotterdam, the Municipal Health Service, Rotterdam area, the Rotterdam Homecare Foundation, and the Stichting Trombosedienst & Arsenenlaboratorium Rijnmond (STAR), Rotterdam. We gratefully acknowledge the contribution of general practitioners, hospitals, midwives and pharmacies in Rotterdam.

The first phase of the Generation R Study was made possible by financial support from the Erasmus Medical Center, Rotterdam, the Erasmus University, Rotterdam, and the Netherlands Organization for Health Research and Development (ZonMw). Additional support was provided by a grant from the Dutch Kidney Foundation (C08.2251).
