Abstract

Disturbances in intracellular calcium homeostasis are likely prominent and causative factors leading to neuronal cell death in Alzheimer’s disease (AD). Familial AD (FAD) is early-onset and exhibits autosomal dominant inheritance. FAD-linked mutations have been found in the genes encoding the presenilins and amyloid precursor protein (APP). Several studies have shown that mutated presenilin proteins can directly affect calcium release from intracellular stores independently of Aβ production. Although less well established, there is also evidence that APP may directly modulate intracellular calcium homeostasis. Here, we directly examined whether overexpression of FAD-linked APP mutants alters intracellular calcium dynamics. In contrast to previous studies, we found that overexpression of mutant APP has no effects on basal cytosolic calcium, ER calcium store size or agonist-induced calcium release and subsequent entry. Thus, we conclude that mutated APP associated with FAD has no direct effect on intracellular calcium homeostasis independently of Aβ production.

Introduction

Alzheimer’s disease (AD) is a progressive neurological disorder characterized by deterioration of cognitive abilities. AD is the most common cause of dementia in the western world, affecting one in ten individuals over 65 and nearly 50% of all persons over the age of 85 [1,2]. According to the predominant amyloid cascade hypothesis, AD pathogenesis is associated with a series of molecular events which leads to the extracellular deposition and aggregation of specific proteolytic fragments of APP. These aggregated protein fragments constitute the core of extracellular senile amyloid plaques, a pathologic hallmark of AD.

In normal physiology, APP is cleaved by a series of enzymes, called secretases, generating proteolytic fragments of various lengths. The principal cleavage event is by γ-secretase, which generates a large soluble ectodomain (APPγ) that is secreted into the extracellular space and a C-terminal fragment (C83) that remains in the membrane [3]. In an alternate processing pathway, holo-APP can be cleaved by β-secretase, resulting in the production of a secreted ectodomain and the membrane-associated C99 fragment [3]. Subsequent cleavage of C99 by γ-secretase produces the neurotoxic Aβ peptide and an intracellular domain (AICD) that is released from the membrane into the cytosol. There are two major forms of the Aβ peptide that differ in length by 2 residues, Aβ42 and Aβ40. The Aβ42 peptide is more prone to aggregation and is considered to be more cytotoxic than the shorter Aβ species [4].

Most cases of AD are sporadic and late-onset, but rare forms of familial AD (FAD) are early-onset and exhibit autosomal-dominant inheritance. The majority of FAD cases are linked to mutations in the presenilin (PS) genes 1 and 2 [5]. Presenilins constitute the catalytic core of γ-secretase, and PS mutations lead to relative overproduction of Aβ42 [6,7,8,9]. FAD-linked mutations have also been found in APP, and depending on the mutation result in increased β-secretase processing, increased Aβ42/Aβ40 ratio, increased propensity of Aβ to form fibrils, or decreased proteolytic clearance of Aβ peptides [10,11,12,13,14,15,16,17,18,19,20].

While it is clear that APP-derived fragments are involved in a proximal step in the pathogenesis of AD, the exact mechanism of neuronal loss in not known. Also, clinical symptoms do not correlate well with amyloid plaque load, suggesting that a certain level of neuronal dysfunction precedes gross architectural changes in AD brain [21,22]. Calcium dyshomeostasis has been implicated as a major contributor to neuronal cell death in AD [23]. Calcium dynamics regulate Aβ production, and Aβ peptides/fibrils directly affect multiple aspects of calcium homeostasis [24]. There is strong evidence that mutated presenilin proteins can directly modulate calcium release from intracellular stores independently of Aβ production [25,26,27], and may also form calcium permeable channels in the endoplasmic reticulum [28]. Similarly, several studies have suggested that APP may directly modulate calcium homeostasis independently of Aβ production [29,30,31]. However, a systematic study of the effects of FAD-associated APP mutants on intracellular calcium homeostasis has not been reported.

Here, we show that overexpression of FAD-linked APP mutants has no effect on basal cytosolic calcium concentration, ER calcium store size, or agonist-induced calcium release and subsequent entry. These results indicate that mutant APP likely does not
contribute mechanistically to alterations in calcium homeostasis in AD independently of Aβ production.

Results

Expression of Different FAD-linked APP Mutants in PC12 Cells

For our studies, we focused on six different well-characterized FAD-linked APP mutants that affect β-secretase cleavage, fibrillization, and γ-secretase cleavage (Figure 1A). The Swedish double mutant makes APP a more favored substrate for β-secretase shunting full-length APP down the amyloidogenic processing pathway [10,11]. The London, Indiana, and V717L mutations favor production of Aβ42 by the γ-secretase [12,13,14,15,16]. The Flemish and Arctic APP mutations increase the propensity for fibrillization and decrease proteolytic clearance of Aβ products [17,18,19,20].

Immunoblot analysis of PC12 cells overexpressing wild-type and mutant APP revealed two bands with approximate molecular weight of 110–120 kDa corresponding to immature and mature forms of the holoprotein (Figure 1B). As APP is trafficked through the secretory pathway, a series of glycosylation events occur leading to a mature, or fully glycosylated, protein with slower mobility on SDS-PAGE. An immunoblot for α/β-tubulin is shown as a loading control (Figure 1C).

ER Calcium Release, Receptor-operated Calcium Entry, and ER Calcium Store Size Are Not Affected by FAD-linked Mutant APP

Calcium release from ER-resident inositol 1,4,5-trisphosphate receptors (IP3Rs) has been proposed to be a critical mediator of calcium dyshomeostasis in AD [25,26,27]. To determine whether mutant APP expression affects IP3R-mediated calcium release, we measured the response of PC12 cells to the purinergic agonist UTP, which selectively activates phospholipase C-coupled P2Y receptors [32]. PC12 cells were co-transfected with yellow fluorescent protein (YFP) and one of the following: empty vector or control, wild-type APP, or one of six FAD-linked APP mutants. To selectively examine IP3R activity and exclude the contribution of calcium entry from the plasma membrane, UTP stimulation was done in calcium free media. As indicated in the representative fura-2 calcium traces in Figure 2A, addition of UTP induces a robust calcium release from the ER into the cytosol in calcium-free media. Peak calcium release in response to UTP did not differ between control cells expressing empty vector, cells expressing wild-type APP, and cells expressing APP mutants (Figure 2B).

Depletion of ER calcium stores by agonist stimulation triggers store/receptor-operated calcium entry (SOC/ROC) through channels in the plasma membrane [33]. Entry through these channels has been proposed to be compromised in fibroblasts expressing mutant presenilins [34]. To determine the effect of FAD-linked APP mutants on receptor-operated calcium entry, we waited until cytosolic calcium levels reached baseline following UTP stimulation in calcium-free medium and replaced the bath solution with calcium-replete medium. As shown in Figure 2C, receptor-operated calcium entry did not differ significantly between control cells expressing YFP alone, cells expressing wild-type APP, and cells expressing any of the six APP mutants tested.

Next, we wanted to determine the effect of FAD-linked mutant APP on ER calcium store size. To directly measure ER calcium content, we utilized ER compartmentalized mag-fura-2 [35,36,37]. As shown in Figure 2D, ER calcium store size did not differ between control cells, wild-type APP-expressing cells, and any of the six APP mutants tested.

Agonist-Induced Calcium Release Is Not Affected by FAD-linked Mutant APP

Mutant presenilins directly modulate calcium release from ER stores [25,26,27]. To address whether mutant APP has similar effects, we monitored the response of PC12 cells to two different doses of UTP. As shown in the representative traces in Figure 3A, addition of subsaturating (10 µM) and saturating (100 µM) doses of UTP resulted in transient increases in cytosolic calcium. There was no difference in the percent of cells that responded to the subsaturating dose (Figure 3B), indicating that there were no significant differences in sensitivity to agonist-induced calcium release. There were also no differences observed in peak calcium release induced by either dose between control, wild-type APP, and the six mutant APP-expressing cells (Figure 3C). By analyzing baseline calcium levels in each condition, we were also

Figure 1. Expression of wild-type APP and different FAD-linked APP mutants in PC12 cells. (A) Schematic diagram depicting the C-terminal portion of APP with secretase cleavage sites indicated in red and locations of FAD-linked mutations marked with asterisks. The transmembrane region is shaded in yellow. The epitope for the anti-Aβ 1–10 antibody (Millipore catalogue # 07-592) is indicated. Specific amino acid substitutions for each mutation are shown with residue numbering corresponding to APP770. (B) Overexpression of APP constructs in PC12 cells. Mock cells were co-transfected with YFP and empty vector. (C) Immunoblot for α/β-tubulin to demonstrate equal loading.

able to determine that resting cytosolic calcium was not altered in cells expressing wild-type APP or FAD-linked mutant APP (Figure 3D).

**Discussion**

The results of these studies indicate that FAD-linked APP mutants do not directly affect calcium homeostasis independently of Aβ production, at least in this model system. Several studies have shown that overexpression of wild-type APP or FAD-linked mutant APP leads to an increase in basal cytosolic calcium concentration and an increase in ER store size. Rojas and colleagues demonstrated that neurons derived from mice possessing three copies of the APP gene have increased resting cytosolic calcium concentration and altered responses to glutamatergic and nicotinic agonists and that these effects could be partially restored by APP knockdown [29]. Cortical neurons from the triple-transgenic (3xTg-AD) mouse model of AD were also shown to have elevated resting cytosolic calcium [30]. Overexpression of the Swedish APP mutant alone was sufficient to cause the same effect. In these studies, cells were taken from young animals prior to plaque development, suggesting that the changes observed represent proximal events in the disease model. In cells from the 3xTg-AD mice, calcium entry as well as release from intracellular stores both contributed to elevated cytosolic calcium levels [30].

It has been shown that agonist-induced calcium release from intracellular stores is disrupted in fibroblasts from APP null mice [31]. This effect is related to a decrease in ER store size and can be rescued by APP constructs containing the APP intracellular domain (AICD), suggesting that this peptide fragment is involved in regulating intracellular calcium stores [31]. Subsequent studies showed that the loss of AICD was associated with decreased levels of ATP, perhaps impairing ER calcium uptake via the sarcoplasmic reticulum calcium ATPase [38]. Other studies have shown that wild-type APP is not directly involved in modulating calcium stores but does mediate the increase in store size that is seen with certain PS mutants and PS deficiency [39]. The effect of PS knockdown on store size was exacerbated in cells expressing the FAD-linked APP mutant V717I, and this effect correlated with increased levels of C99 in these cells [39].
Here, we demonstrated that FAD-linked APP mutations do not directly alter calcium signaling when overexpressed in PC12 cells. These results suggest that a different mechanism must exist for the perturbations in intracellular calcium that are observed in forms of FAD that are linked to mutations in APP. Most likely, these effects are mediated directly by Aβ and not the APP holoprotein. Furthermore, our results promote the hypothesis that the disruption in calcium signaling seen with PS mutants is independent of the role for PS in APP cleavage, and may instead reflect a general role for PS in the maintenance of intracellular calcium homeostasis.

Methods

Cell Lines

PC12 rat pheochromocytoma cells were purchased from ATCC. They were cultured in Dulbecco's Modified Eagle's Medium supplemented with 10% fetal bovine serum, 5% horse serum, 100 U/ml penicillin, and 100 μg/ml streptomycin.

Generation of APP Mutants

Point mutations in human APP695 (kindly provided by Dr. Hui Zheng, Ph.D., Baylor College of Medicine) were accomplished with the QuickChange Site-directed Mutagenesis Kit (Stratagene, La Jolla, CA) according to manufacturer's instructions. Forward primers were as follows:

- Swedish 5'-GGAGATCTCTGAAGTGAACCTGGATGCA-GAATTCC-3';
- Flemish 5'-CAAAAATTGGTGTTCTTTGGAGAAGATGTGGG-3';
- Arctic 5'-GGTGTTCTTTGCAGGAGATGTGGTCAAC-3';
- London 5'-CATAGCGACAGTGATCATCATCACCTTG-GTGATGC-3';
- Indiana 5'-CATAGCGACAGTGACCTTCATCACACCTTGG-GTGATGC-3';
- V717L 5'-CATAGCGACAGTGTTCATCACACCTTGG-GTGATGC-3'.

The reverse primers were the exact reverse complement.

Calcium Imaging

Calcium measurements were performed as previously described [40]. PC12 cells were cultured on 25 mm coverslips overnight, and were co-transfected with APP and yellow fluorescent protein (YFP) at a 4:1 ratio. Under these conditions, we have found that all YFP-positive cells express both proteins [41]. For all experiments, transfection efficiency as determined by fluorescence microscopy was greater than 50%. Similar results were obtained by imaging APP-GFP fusion proteins (data not shown). For measurement of cytosolic calcium, cells were loaded with fura-2 as described elsewhere [40] for 30 minutes at 25°C.
measurements, cells were loaded with 5 μM mag-fura-2 for 20 minutes at 37°C followed by a 60-minute incubation at 37°C in dye-free extracellular medium (107 mM NaCl, 7.2 mM KCl, 1.2 mM MgCl₂, 1 mM CaCl₂, 11.5 mM glucose, 0.1% bovine serum albumin, and 20 mM HEPEs 7.2). Coverslips were transferred to a microscope and the plasma membrane was subsequently permeabilized by a brief exposure to 0.01% saponin to release cytoplasmic dye before exchanging the solution with intracellular solution (135 mM KCl, 3 mM MgATP, 2 mM MgCl₂, 0.4 mM CaCl₂, 1 mM EGTA, and 20 mM HEPEs 7.1) as described [35]. All fields were imaged randomly, and all YFP-positive cells in a given field were imaged and quantified in the data analysis. The number of cells analyzed is indicated above each data point. Fura-2/mag-fura-2 and YFP images were acquired every 3 seconds during acquisition on a Nikon TE2000 inverted microscope using a Nikon 60X oil immersion SuperFluor objective with a 1.3 numerical aperture. All imaging was performed at 25°C. Images were captured with a Roper Scientific CoolSNAP HQ monochrome camera. Rapid filter changes for ratiometric imaging were computer controlled via a Ladt MAC6000 rapid filter wheel and changer and MetaFluor acquisition and analysis software. Raw data was acquired with MetaFluor, analyzed in Excel, and graphed in SigmaPlot.

Statistical Analysis
All experiments were performed a minimum of three times and presented as the mean ± standard error. Single cell traces from each coverslip were pooled and averaged for each data point. Total number of single cell traces is indicated over each bar. Statistical comparisons from the pooled data were performed between groups using the student’s t test. Statistical significance was considered at p values <0.05.

Acknowledgments
We thank Hui Zheng, Ph.D., Baylor College of Medicine, for providing the human APP695 cDNA.
