ABSTRACT: One of the challenges in the field of biosensors and biofuel cells is to establish a highly efficient electron transfer rate between the active site of redox enzymes and electrodes to fully access the catalytic potential of the biocatalyst and achieve high current densities. We report on very efficient direct electron transfer (DET) between celllobiose dehydrogenase (CDH) from Phanerochaete sordida (PsCDH) and surface modified single walled carbon nanotubes (SWCNT). Sonicated SWCNTs were adsorbed on the top of glassy carbon electrodes and modified with aryl diazonium salts generated in situ from p-aminobenzoic acid and p-phenylenediamine, thus featuring at acidic pH (3.5 and 4.5) negative or positive surface charges. After adsorption of PsCDH, both electrode types showed excellent long-term stability and very efficient DET. The modified electrode presenting p-aminophenyl groups produced a DET current density of 500 μA cm⁻² at 200 mV vs normal hydrogen reference electrode (NHE) in a 5 mM lactose solution buffered at pH 3.5. This is the highest reported DET value so far using a CDH modified electrode and comes close to electrodes using mediated electron transfer. Moreover, the onset of the electrocatalytic current for lactose oxidation started at 70 mV vs NHE, a potential which is 50 mV lower compared to when unmodified SWCNTs were used. This effect potentially reduces the interference by oxidizable matrix components in biosensors and increases the open circuit potential in biofuel cells. The stability of the electrode was greatly increased compared with unmodified but cross-linked SWCNTs electrodes and lost only 15% of the initial current after 50 h of constant potential scanning.

Efficient electron transfer between redox enzymes and electrodes is a major issue in the development of biosensors and biofuel cells. Most commonly, large distances (above 20 Å) prevent direct electron transfer (DET) between the prosthetic group in the active site and the electrode.¹² Mediated electron transfer (MET) employs redox mediators to shuttle redox equivalents or allow electron hopping between the enzyme and the electrode and has been widely applied to solve this problem. Good sensitivities and high current densities have been demonstrated for different biosensors and biofuel cells based on MET.²⁻⁸ On the other side, DET between the enzyme and the electrode surface would obviate problems associated with MET (e.g., leaking or limited stability of redox mediators, expensive heavy metal complexes, potential toxicity of mediator), allow a more simple design of the electrode, and reduce the number of additional components, which have to be added and optimized.⁹ When implanted or deposited after use, DET based biosensors or biofuel cells cannot release environmentally hazardous, potentially toxic mediators or their degradation products.

It is well-known that DET either requires a close proximity of the active site of the redox enzyme to the protein surface (e.g., cytochrome c peroxidase)³,¹⁰ or needs a connection with the protein surface by a built in electron transfer pathway constructed by a chain of redox active cofactors (e.g., NiFe hydrogenaes)¹,²,¹¹ or by an electric wire.¹²⁻¹⁶ DET is therefore rarely observed; it was shown for only 5% of the currently known redox enzymes.³,¹⁷ Moreover, even if the prerequisites for DET are given, the correct orientation of the active site and vicinity to the electrode surface are required for high electron transfer rates.² DET is therefore difficult to achieve, and an optimized
electrode surface is required. The most commonly employed electrode modifiers for DET are self-assembled monolayers (SAM) of functionalized thiols on gold, which facilitate the ordered immobilization of proteins.16–22 Similar to the modification with thiols, but more stable and with the possibility to be employed on both metal and carbon surfaces, is the modification with functionalized aryldiazonium salts.23–26 Corgier et al. introduced in 2005 the use of diazonium-modified antibodies for the direct electrically addressable immobilization of proteins.27 In 2006, Polsky et al. showed a high direct heterogenous electron transfer for horseradish peroxidase covalently bonded to carboxyl terminated aryldiazonium salt modified electrodes.28 More recently, Blanford et al. used aryldiazonium coupling to attach anthracene-2-diazonium on a glassy carbon electrode surface to create the equivalent of an “electric plug” to achieve high DET currents with Pycnoporus cinnabarinus laccase.29 In recent years, the currents obtained from both DET and MET based electrodes were increased by modifications based on nanomaterials such as single walled carbon nanotubes (SWCNTs),30,31 These can improve current densities by two mechanisms: (i) by functioning as nanoscaled electrical wires, which facilitate the contact of the active sites of redox enzymes32,33 and (ii) by generating a large surface area for protein binding.34–36 In 2001, Bahr and Tour modified SWCNTs with in situ generation of functionalized aryldiazonium species.35

Cellobiose dehydrogenase (EC 1.1.99.18, CDH) is one of the redox enzymes capable of DET, which is a result of its two-domain structure.36 The extracellular, glycosylated flavocytochrome is formed by basidiomycete and ascomycete fungi and is believed to be involved in lignocellulose degradation. Depending on the origin, CDHs show different substrate specificities, but in general, they all oxidize β-1,4-linked di- and oligosaccharides (e.g., cellobiose, cellooligomers, and lactose). Some ascomycete CDHs may also oxidize monosaccharides (e.g., glucose). In the catalytic reaction, $2H^+ / 2e^-$ are donated to the FAD cofactor in the larger flavodehydrogenase domain (DHCDH). The electrons are transferred either directly from the FAD to one- or two-electron acceptors or sequentially by intramolecular electron transfer (IET) to the haem $b$ cofactor located in the smaller cytochrome domain (CYTCDH), which can act as an electron transfer mediator between DHCDH and an electrode (DET step). Because of their carbohydrate oxidizing activity, CDHs have been employed in DET based amperometric lactose biosensors37,38 and recently also in lactose or glucose powered biofuel cells.39–42 CDH from the basidiomycete Phanerochaete sordida (PsCDH) is an acidic enzyme with respect to its p$\text{H}$ optima and its isoelectric point (pI).41,42 To improve the electron transfer efficiency between CYTCDH and electrodes, SWCNTs were adsorbed on the top of glassy carbon electrodes and further modified with in situ generated aryldiazonium salts starting from p-aminobenzoic acid and p-phenylenediamine. We have chosen phenyl-COOH (COOH-PD) and phenyl-NH2 (NH2-PD) moieties, because they are present in their deprotonated (carboxyphenyl group pK$_a$ = 2.8) or protonated state (aminophenyl group pK$_a$ = 4.6) at the investigated pH values of 4.5 and 3.5, respectively. PsCDH was specifically chosen for its very good DET properties,40,41,42,43,44,45 and the low isoelectric point (a relatively high abundance of acidic amino acids). This study aimed at investigating the effect of negatively/positively charged SWCNTs on the DET characteristics obtained with a negatively charged protein moiety (CYTCDH) with respect to current density and stability of the produced electrodes. This study is also motivated by the fact that third generation biosensors and biofuel cell electrodes exhibit much lower current densities than their equivalents based on MET. If there is a way to drastically increase the current density through a higher percentage of immobilized redox enzymes orientated toward DET, much would be gained both for analytical as well as other types applications for third generation based bioelectrodes.

**EXPERIMENTAL PART**

Reagents and Equipment. All reagents were used as received, and aqueous solutions were prepared with Milli-Q water (>18 M$\Omega$ cm$^{-1}$, Millipore, Sydney, Australia). Ferricyanide (K$_3$Fe(CN)$_6$), hexaminenathenium(III) chloride (Ru(NH$_3$)$_3$Cl$_2$), p-aminobenzoic acid, polyethylene glycol diglycidylether (PEGDGE), sodium nitrate (NaNO$_2$), dichloroindophenol (DCIP), and 1,4-benzoquinone (BQ) were obtained from Sigma Chemical Co. (Sydney, Australia). p-Phenylenediamine was from Hopkin and Williams LTD (Glenmilles, PA, USA). Single walled carbon nanotubes (SWCNT) were HiPco tubes from Carbon Nanotechnologies Inc. (Houston, TX, USA). All electrochemical measurements were performed with a BAS-100B electrochemical analyzer (Bioanalytical System Inc. West Lafayette, IL, USA) and a conventional three-electrode system using 3 mm diameter modified glassy carbon (GC) electrodes (BAS) working electrodes, a homemade platinum plug as counter electrode, and an Ag/AgCl (3 M KCl) reference electrode. The potential is in all cases referred to the normal hydrogen reference electrode (NHE). The current densities were calculated with respect to the geometric electrode area. Unless otherwise stated, cyclic voltammetry (CVs) was carried out in 0.1 M sodium acetate buffers of various pH values. Buffer solutions were degassed by sparging with argon for at least 15 min prior to data acquisition and were blanketed with argon during the entire experiment.

**Electrode Preparation and Electrochemical Measurements.** GC electrodes were polished with aqueous alumina slurries ($\text{Al}_2\text{O}_3$) by stepwise decreasing the particle size (1 to 0.05 μm) on wet microcloth pads (Buehler, Lake Bluff, IL, USA) using Milli-Q water. The electrodes were thoroughly rinsed with and sonicated in Milli-Q water for 5 min between polishing steps. Ten μL of a 30 mg mL$^{-1}$ overnight sonicated aqueous solution of SWCNTs was dropped on the top of a GC electrode dried in a desiccator. Carboxylate and amine groups on the GC electrodes were introduced by electrochemical reduction of the arylazidation cation generated in situ from either p-aminobenzoic acid (COOH-PD) or p-phenylenediamine (NH$_2$-PD).45 Briefly, 5 mM (final concentration) NaNO$_2$ was added to a 5 mM acidic aqueous solution (0.5 M HCl) of the aryl amine (1 mM) to generate the arylazidation cation. The solution was kept in complete darkness in an ice bath and allowed to react for 5 min under a nitrogen stream and stirring. Surface derivatization was carried out using electrochemical reduction by scanning the SWCNTs-GC working electrode from 1.2 to −0.8 V vs NHE at a rate of 100 mV s$^{-1}$ for 2 cycles in the arylazidation cation-generating solution. The resulting modified electrodes were removed and rinsed with large volumes of water and dried under a stream of nitrogen. Enzyme-modified electrodes were prepared by allowing 10 μL of a Phanerochaete sordida cellobiose dehydrogenase (PsCDH) solution to adsorb on the top (6.55 mg/mL$^{-1}$ 206 U/mL$^{-1}$ produced according the method from Ludwig et al.46) to adsorb on the top of the SWCNTs arylazidation modified GC electrodes (Figure 1). The electrodes were allowed to dry overnight at 4 °C under controlled humidity. The activity of PsCDH was 140 U mL$^{-1}$, the protein concentration

The electrodes were allowed to dry overnight at 4 °C under controlled humidity. The activity of PsCDH was 140 U mL$^{-1}$, the protein concentration.
was 4.2 mg mL$^{-1}$, and the specific activity was 33 U mg$^{-1}$. The cultivation and purification of the enzyme was the same as described for *Trametes villosa* CDH.

**Steady-State Kinetic Measurements.** The pH-dependent activity of *Ps*CDH in solution was measured using either the one-electron acceptor cytochrome $c$ or the two-electron acceptors DCIP or BQ in 0.1 M sodium citrate buffer (measured pH range of 2.9–6.4) containing 30 mM lactose as electron donor according to published methods. The apparent $K_M$ value of *Ps*CDH for lactose was measured spectrophotometrically at 30°C employing different lactose concentrations (0.1–50 mM) and cytochrome $c$ (20 μM) as saturating electron acceptor and calculated by linear least-squares regression using Sigma Plot 11 (Systat Software, San Jose, CA, USA). The $k_{cat}$ was calculated from the $V_{max}$ value by applying the molecular mass of *Ps*CDH (81 000 Da), and the protein concentration was measured by the Bradford method using a manufactured protein assay reagent (Fermentas, St. Leon-Rot, Germany) and bovine serum albumin as protein standard.

**Isoelectric Focusing.** To determine the isoelectric point of *Ps*CDH and its proteolytic cleavage products (papain cleavage), samples containing either the native enzyme or the flavodehydrogenase domain (DH$_{Ps*CDH}$) and the cytochrome domain (CYT$_{Ps*CDH}$) were applied on a Multiphor II system (GE Healthcare) using precast gels (Clean gel IEF) rehydrated with carrier ampholytes in the range between pH 2.0 and 9.0 (GE Healthcare and Serva, Heidelberg, Germany). The IEF protein standard (3–10 from Serva was used to determine the pI values. Enzymatically active bands were visualized by active staining. Therefore, the gel was first soaked in 3 mM DCIP solution before pouring 300 mM lactose solution over the surface. Shortly after, colorless bands appeared because of reduction of DCIP into its leucoform. Afterward, the gel was transferred into 20% acetic acid for overnight protein fixation. Proteins were visualized by silver staining.

**RESULTS AND DISCUSSION**

**Aryl Diazonium Coupling.** The process is based on aryl amines, which are converted into aryl diazonium salts by treatment with hydrochloric acid and nitrite at ice temperature. Subsequently, the aryl group is covalently attached to the electrode surface by electrochemical reduction, releasing N$_2$. GC electrodes were used as robust supports for physical absorption of SWCNTs and further modification with the introduction of amine groups, which are protonated (positively charged) at pH 3.5 and carboxylate groups, which are deprotonated (negatively charged) at pH 4.5. Deposition of NH$_2$-PD and COOH-PD, respectively, was achieved by two sequential potential CVs from 1.2 to −0.8 V vs NHE in aqueous solution containing 0.5 M HCl and 5 mM NaNO$_2$. Two consecutive CVs are shown in Figure 2a for the NH$_2$-PD modification of a...
SWCNTs-GC electrode and in Figure 2b for a corresponding COOH-PD one. The first cycle in Figure 2a presents two reduction peaks. During the second cycle, only a small reduction current at a lower potential is present, suggesting the presence of the grafted layer. The reduction of the p-aminobenzoic acid moiety is exhibited in Figure 2b and characterized by a well-defined, reproducible, and irreversible reduction peak at 0 mV vs NHE in the first cycle. The lower current obtained in the second cycle is evidence of surface saturation and suggests that a layer of covalently bound molecules was formed.

Presence of the Grafted Layer. To demonstrate the presence of the grafted layer and investigate its properties, cyclic voltammetry with soluble electroactive species was performed and the influence of the electrode modification on the oxidation/reduction processes of Ru(NH$_3$)$_6^{3+}$ and Fe(CN)$_6^{4-}$ was investigated. Figure 3a shows the CVs recorded with the NH$_2$-PD/SWCNTs-GC electrode in the presence of 5 mM Ru(NH$_3$)$_6^{3+}$ at pH 3.0 (—) and at pH 6.0 (red —). The oxidation/reduction process of Ru(NH$_3$)$_6^{3+}$ presents a quasi-reversible behavior at pH 6.0 with an apparent redox potential of 0 mV vs NHE. At pH 3.0, the NH$_2$-PD/SWCNTs-GC electrode shows a blocking behavior. The increase of positive charges on the NH$_2$-PD modified electrode when decreasing the pH from 6.0 to 3.0 leads to electrostatic repulsion between Ru(NH$_3$)$_6^{3+}$ and the modified electrode surface. The surface pK$_a$ of NH$_2$-PD/SWCNTs-GC should be close to that of surface bound p-aminothiophenol and to that of aniline adsorbed on gold pK$_a$ = 4.6. A very large fraction of the amino groups will therefore be positively charged at pH 3.5 but neutral at pH 6.0. It could be argued that p-phenylenediamine can form a bifunctional diazonium salt, which should attack the graphite surface in an uncontrollable way. However, it was shown very recently that upon exposure to sodium nitrite only one of the amine groups is converted. In Figure 3b, results from a COOH-PD/SWCNTs-GC electrode in the presence of Fe(CN)$_6^{3+/4+}$ at pH 4 (—) and at pH 2 (red —). Figure 3. (a) Cyclic voltammograms recorded at NH$_2$-PD/SWCNT-GC electrode in the presence of 5 mM Ru(NH$_3$)$_6^{3+}$ in acetate buffer at pH 3.0 (—) and at pH 6.0 (red —). (b) Cyclic voltammograms recorded at COOH-PD/SWCNT-GC electrode in the presence of 5 mM Fe(CN)$_6^{3-/4-}$ at pH 4 (—) and at pH 2 (red —).

Molecular and Catalytic Properties of P. sordida CDH. The isoelectric points (pI) of PsCDH and DH$_{PsCDH}$ were determined by isoelectric focusing using active staining and silver staining (Figure 4). The pI value of the purified PsCDH was estimated to be 4.1; for the proteolytic cleavage product DH$_{PsCDH}$, a pI value
of 5.7 was found. Additionally, minor bands were found in the silver stained gel, one representing a PsCDH isoform (pI = 4.0) and the other (pI = 4.8) could be the proteolytic cleavage product of either the minor isoform or DH<sub>PsCDH</sub> itself. Both bands are active and overemphasized by the sensitive active staining, which even shows a band for glucose oxidase in lane 1 (from the pI standard) although lactose was used as substrate. No CYT<sub>PsCDH</sub> band was found, it is likely to be further degraded by papain. By comparison of the values obtained for PsCDH to the values of the well characterized CDH from <i>P. chrysosporium</i> (CDH 4.18, DH<sub>PsCDH</sub> 5.45, CYT<sub>PsCDH</sub> 3.42),<sup>50</sup> it can be deduced that the pI of CYT<sub>PsCDH</sub> must be even lower than the pI of CYT<sub>PsCDH</sub> to compensate for the less negatively charged DH<sub>PsCDH</sub>.

The pH-dependent activity for different electron acceptors was measured within the pH range of 2.9—6.4 (Figure 5). With the two-electron acceptors, BQ and DCIP, PsCDH exhibits a plateau-shaped pH profile between pH 3.5 and 5.0, which ensures that lactose turnover at DH<sub>PsCDH</sub> is relatively constant at pH 3.5 and 4.5. In contrast, the one-electron acceptor cytochrome <i>c</i> which interacts solely with CYT<sub>PsCDH</sub> shows a bell-shaped profile with a pH optimum at pH 4.0. The IET is strongly pH-dependent and decreases dramatically above pH 4.5 (34% residual activity at pH 5.0, 8% at pH 5.5). However, at the investigated pH values, the IET is fairly constant with 95% of the maximum value at pH 3.5 and 80% at pH 4.5, which ensures that DET currents measured on the electrodes are not influenced by rate limiting or vastly differing IET rates.

The <i>K<sub>M</sub></i> value of PsCDH for lactose was determined to be 0.7 mM, and the <i>k<sub>cat</sub></i> was 45 s<sup>−1</sup>, values which compare well with data reported for <i>P. chrysosporium</i> CDH measured for lactose with cytochrome <i>c</i> as electron acceptor at room temperature (K<sub>M</sub> = 0.63 mM, k<sub>cat</sub> = 28.8 s<sup>−1</sup>).<sup>31</sup> The lactose concentration used for all further experiments (5 mM) is therefore 7.1-fold the <i>K<sub>M</sub></i> value of the enzyme and ensures a high catalytic substrate turnover (~88% of V<sub>max</sub>). It is, on the other side, sufficiently low to avoid significant background current by nonspecific oxidation as reported for a SWCNT modified electrode and a lactose concentration of 100 mM.<sup>32</sup>

**Effect of NH<sub>2</sub>-PD and COOH—PD Modifications on DET of PsCDH.** PsCDH has an overall isoelectric point of 4.1, but its two domains differ strongly in their individual pI values. Whereas DH<sub>PsCDH</sub> is less negatively charged (pI = 5.7), CYT<sub>PsCDH</sub> has an isoelectric point below 3.5 and presents many negatively charged amino acid residues on its surface (when assuming a high structural similarity with <i>P. chrysosporium</i> CYT<sub>CDH</sub> PDB ID: 1D7B).<sup>52</sup> We sought to take advantage of this uneven distribution of charges and investigate the influence of charged electrode surfaces on the possibility to orientate the enzyme to achieve efficient DET. Moreover, the pH optimum for activity and IET between pH 3.5 and 4.5 allowed us to neglect their influence on DET within this pH range.

To obtain high currents, SWCNTs were used as nanoscaled electrical wires to facilitate DET between the CYT<sub>CDH</sub> of the native enzyme and the underlying electrode and to provide a large surface area for enzyme immobilization.<sup>32,33</sup> Moreover, aryldiazonium coupling was used to create specific functional charged groups on the electrode nanowire surface to possibly increase the interaction forces and orientate the enzyme on the surface. The scheme in Figure 1 shows the modification route of SWCNTs-GC electrodes with p-amino benzoic acid or p-phenylenediamine and subsequently with PsCDH.

In Figure 6a, the CV of a PsCDH modified COOH-PD/SWCNTs-GC electrode shows the DET current in the presence and absence of substrate in acetate buffer, pH 4.5. In the CV in the absence of substrate, two redox waves can be observed. The first redox wave at −50 mV can be referred to FAD from DH<sub>PsCDH</sub> while the second one at a more positive potential (100 mV) can be assigned to the haem <b>in</b> CYT<sub>PsCDH</sub>. When 5 mM substrate is added, the onset of the electrocatalytic current for lactose oxidation can be observed around 70 mV vs NHE with a maximum increase in the slope of the wave at 170 mV and the current steadily increases up until around 200—210 mV and after that starts to level off. No electrocatalytic current was observed from the DH<sub>FAD</sub> domain. Therefore, the wave seen at −50 mV in the CV without substrate is most likely caused by FAD released from the protein or a denaturated domain, as we

**Figure 5.** Activity versus pH profiles of PsCDH using (—) cytochrome <i>c</i>, (□) DCIP, and (●) BQ. The turnover numbers are given for the different electron acceptors. For lactose, the turnover number would be the same in the case of the two-electron acceptors but only half the value in the case of cytochrome <i>c</i> (stoichiometry = 2).

already reported in refs 32 and 33, rather than DET between the catalytically active site of the DHFAD domain and the electrode.

The electrocatalytic current density curve for substrate oxidation reaches a maximum at 150 μA cm⁻². This value is comparable to the electrocatalytic current obtained for a PsCDH SWCNT-GC electrode (results not shown) and for a PsCDH SWCNT modified pyrolytic graphite electrode⁵⁻² (results not shown). These similar results are not surprising, since it is known that SWCNTs present already some carboxyl groups on their surface, and the COOH-PD modification is only expected to saturate the surface with such functionalities. The CVs reported here were obtained at a scan rate of 1 mVs⁻¹. At this scan rate, there is still a noticeable capacitive current due to the high surface area of the electrode. When the amount of enzyme solution used for electrode preparation was varied (5 or 10 μL), the maximum electrocatalytic current was constant, indicating an excess of enzyme.

The modification of the SWCNTs-GC electrode with NH₂-PD and PsCDH led to different results compared with earlier reported data for SWCNTs,²³,3², or the COOH-PD/SWCNTs-GC from this study, especially with respect to the very high catalytic current density obtained (Figure 6b). In fact, a current density of more than 500 μA cm⁻² was obtained when the electrode was immersed in a solution containing 5 mM lactose in acetate buffer at pH 3.5 as seen in Figure 6b. This corresponds to an approximately 3.5-fold increase in current with respect to the modification with COOH-PD/SWCNTs. The electrocatalytic current for lactose oxidation can be observed to start at around 0 mV with a maximum for the wave at around 100 mV vs. NHE. In the CV without substrate, only a well-defined wave with a midpoint potential at 70 mV can be observed. The onset of the catalytic anodic wave for lactose oxidation is around 50 mV lower than what we obtained for the COOH-PD/SWCNTs-GC (70 mV) and previously for unmodified SWCNTs (75 mV at pH 3.5).²³,5³ The reason for the lower onset of the anodic wave for lactose oxidation and for the haem b midpoint potential might be the obvious extremely good DET communication between CytₚCDH and the NH₂-PD/SWCNTs layer. The low isoelectric point of CytₚCDH (pI < 3.5) and the high surface concentration of negatively charged amino acid residues already at pH 3.5 can explain why a NH₂-PD modification (together with the already existing COOH groups) can create a less electrostatic repulsive environment for CytₚCDH and enhance DET. Similar current densities for PsCDH (500 μA cm⁻² at pH 4.0) were obtained before only when a mediated system based on an osmium redox polymer in combination with PsCDH/SWCNTs modified pyrolytic graphite electrodes was used,³⁵ where the electrons are shuttled in a mediated mode from the enzyme to the electrode by the osmium redox polymer that was cross-linked to the enzyme. Previous studies of both basidiomycete (class I) and ascomycete (class II) CDH on thiol modified gold electrodes ²¹,²²,²⁵,³⁵ have revealed that a positively charged headgroup on the SAM yields much better electrochemical communication with the enzyme than a negatively charged SAM. As expected, the good electrochemical communication between PsCDH and the NH₂-PD modified surface is in agreement with previous results, shown for PsCDH at positively charged 4,4'-aldrithiol SAM modified gold electrodes. ²² Two mechanisms can explain the enhanced current observed at NH₂-PD/SWCNT modified electrodes. First, PsCDH can be orientated in a better way for DET by electrostatic forces from the positively charged SWCNT surface. This may also lead to that a higher percentage of the immobilized CDH molecules are orientated for DET with the electrode material. Second, the electrostatic repulsion between the negative surface charges of unmodified or COOH-PD SWCNTs and the also negatively charged CytₚCDH at low pH might reduce the DET rate.

**Stability Measurements.** When investigating the stability of PsCDH NH₂-PD/SWCNTs-GC electrodes in 5 mM lactose at pH 3.5, it performed extremely well. The catalytic current decreased only by 15% in 50 h during continuous recording of multicycle voltammograms at a scan rate of 0.1 mV s⁻¹ between −0.2 and 0.4 V. In Figure 7, 15 scans are shown, which cover a time span of 50 h. Every 10 h, the solution was exchanged for a freshly prepared lactose solution. These results were obtained without a cross-linker. The long-term stability of the electrode was neither positively nor negatively affected when a cross-linker (polyethylene glycol diglycidylether, PEGDGE) was added in a control experiment. This is different to previous reports for CDH/SWCNTs modified carbon electrodes, where always a poor long-term stability was observed in the absence of a cross-linker. The NH₂-PD modification seems to prevent the release of PsCDH from the SWCNTs layer, which is most probably due to attractive electrostatic interactions. Also, in this case, for the COOH-PD/SWCNTs modification, no cross-linker had to be added, suggesting an environment which strongly binds PsCDH and supports its stability. The stability was much higher than what has been reported before for PsCDH cross-linked to SWCNTs modified pyrolytic graphite electrodes working under DET conditions (20% decrease after 12 h when scanning at a scan rate of 0.1 mV s⁻¹ between 294 and 394 mV).³² A comparable stability to the one reported here was only exhibited previously for PsCDH cross-linked to an Os redox polymer and SWCNTs on graphite working under MET conditions (33% decrease after 100 h of running multicycle voltammograms at different pH values).³³ We have previously seen that, when increasing the ionic strength of the supporting electrolyte, then the DET response current rather increases than decreases,³⁶ as could have been expected if the interaction between the adsorbed enzyme and the electrode surface is solely based on electrostatic interactions. Obviously, the influence of the ionic strength is much more complex, as was also recently shown for another redox enzyme, sulfit oxidase, when immobilized onto SAM-coated silver electrodes³⁵ and is currently under intensive studies.

**CONCLUSIONS**

In PsCDH modified GC electrodes, both the COOH-PD/SWCNT and the NH₂-PD/SWCNT modifications were shown to provide a favorable environment for enzyme deposition. Also, the long-term stability of the modified electrode was positively affected by the aryl diazonium salt modification. We can report a loss of 15% of the original activity after 50 h of cycling the
COOH-PD/SWCNTs-GC electrode resulted in a lower current density (150 μA cm⁻², 5 mM lactose, pH 4.5) than the COOH-NH₂-PD/SWCNTs-GC electrode exhibiting a current density of 500 μA cm⁻² (5 mM lactose, pH 3.5). We conclude that the strongly negatively charged Cyt₆PcdH interacts better with the positively charged surface of NH₂-PD-modified electrodes. To the best of our knowledge, this is the first time that such a high current density is reported for an oxidizing enzyme modified electrode working under DET conditions. Similar current densities were previously reported only for enzymes working in MET conditions. Moreover, the onset of the electrocatalytic current for lactose oxidation started at a potential more than 50 mV lower than when the SWCNTs-GC electrodes were modified with COOH-PD.
