Abstract

New exact upper and lower bounds are derived on the spectrum of the square of the hermitian Wilson Dirac operator. It is hoped that the derivations and the results will be of help in the search for ways to reduce the cost of simulations using the overlap Dirac operator. The bounds also apply to the Wilson Dirac operator in odd dimensions and are therefore relevant to domain wall fermions as well.
Introduction

Let $D(m)$ denote the continuum Euclidean Dirac operator where the real parameter $m$ is the fermion mass. In even dimensions $d$ a generalization of $\gamma_5$ exists and shall be denoted by $\gamma_{d+1}$. $D(0)$ is antihermitian and anticommutes with $\gamma_{d+1}$. Then, $H(m) = \gamma_{d+1}D(m)$ is hermitian. $H(m)$ will be referred to as the hermitian Dirac operator. A characteristic property of this operator is the range of its spectrum as a function of the real mass parameter $m$. Since $H^2(m) = D^\dagger(m)D(m)$ it is meaningful to consider the spectrum of $H^2(m)$ both in even and odd dimensions.

Figure 1 displays the familiar spectral structure of $H(m)$ in the continuum in an arbitrary fixed gauge background. The boundaries shown come from rigorous lower bounds on the spectrum of $H^2(m)$. These bounds hold for any gauge background and are often saturated, for example in the case that the gauge background is trivial, or in the case that it consists of a gauge field carrying non-zero topology. There is no upper bound on $H^2(m)$, and the spectrum will indeed increase indefinitely in any fixed smooth gauge background. All this holds also on a compact manifold, henceforth taken to be a flat torus.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure1}
\caption{Spectrum of the Dirac Hamiltonian in the continuum. All oblique lines have slopes $\pm 1$.}
\end{figure}

The objective of this paper is to clarify what happens when the massive Dirac Hamiltonian is put on the lattice following Wilson’s prescription. The most fundamental feature of a lattice operator is that its spectrum is absolutely bounded from above - this is how
the lattice acts as a regulator. However, lower bounds obeyed by the hermitian Wilson Dirac operator, \( H_W^2(m) \), are also very important, because often we wish to use \( H_W(m) \) to put massless, or almost massless quarks on the lattice.

When the gauge background is trivial, \( H_W(m) \) can be explicitly diagonalized and one finds the spectral structure shown in Figure 2. A simpler derivation is contained in what follows.

![Figure 2](image)

**Figure 2** Spectrum of the Wilson Dirac Hamiltonian on the lattice for \( d=4 \). All oblique lines have slopes ±1.

When the gauge field is turned on the figure gets distorted. The upper bound on \( H_W^2(m) \) remains unchanged, and so does the lower bound for positive values of the mass parameter \( m \). Changes occur only for \( m < 0 \) and for the lower bound of \( H_W^2(m) \). So long we are close to the trivial case the distortion is small: it amounts to the replacement of the string of rhombi in Figure 2 by a string of smaller rhombi, inscribed into the ones we have in Figure 2. The new rhombi no longer touch each other. As \( m \) is varied, eigenvalues of \( H_W(m) \) can cross zero in the intervals that open up, separating the rhombi. When the gauge background is random enough the internal rhombi close up completely and very low
eigenvalues of $H^2_W(m)$ are no longer excluded [1] for any mass in the segment $(-2d,0)$. For any gauge background the figure stays mirror symmetric about the $m = -d$ vertical line.

Although we focus on even dimensions here, so long we phrase the results for the Wilson Dirac operator itself and not its hermitian version, they hold for odd dimensions as well. In particular, the five dimensional case applies to domain wall formulations of QCD.

**Notations and Conventions**

Let us start by establishing our notation. We are working on a $d$-dimensional hypercubic lattice. When comparing to the continuum the lattice spacing is denoted by $a$. On its links we have $SU(n)$ matrices $U_\mu(x)$ which make up the gauge background the fermions interact with. $\mu = 1,2,\ldots d$ denotes positive directions and $x$ denotes a lattice site. The lattice is finite.

The fermions are vectors $\psi_\alpha^i(x)$. $\alpha$ is a spinorial index, $i$ is a gauge group index and $x$ is a lattice site. The action on the fermions is described in terms of several unitary operators. First are the Euclidean Dirac $\gamma_\mu$’s which act only on spinorial indices. Second come the directional parallel transporters $T_\mu$ which act on the site index and the group index. They are defined by:

$$T_\mu(\psi)(x) = U_\mu(x)\psi(x + \hat{\mu}).$$

A third class of unitary operators implements gauge transformations, each characterized by a collection of $g(x) \in SU(n)$ acting on $\psi$ pointwise, and only on the group indices. The action is represented by a unitary operator $G(g)$ with $(G(g)\psi)(x) = g(x)\psi(x)$. The $T_\mu$ operators are “gauge covariant”,

$$G(g)T_\mu(U)G^\dagger(g) = T_\mu(U^g),$$

where,

$$U^g_\mu(x) = g(x)U_\mu(x)g^\dagger(x + \hat{\mu}).$$

The variables $U_\mu(x)$ are distributed according to a probability density that is invariant under $U \rightarrow U^g$ for any $g$.

The lattice replacement of the massive continuum Dirac operator, $D(m)$, is an element in the algebra generated by $T_\mu$, $T_\mu^\dagger$, $\gamma_\mu$. Thus, $D(m)$ is gauge covariant. For $U_\mu(x) = 1$ the $T_\mu$ become commuting shift operators.
The Wilson Dirac operator, \( D_W(m) \), is the sparsest possible analogue of the continuum massive Dirac operator which obeys hypercubic symmetry. Fixing the so called \( r \)-parameter to its preferred value \( (r = 1) \), \( D_W(m) \) can be written as:

\[
D_W = m + \sum_{\mu} (1 - V_\mu); \quad V_\mu^\dagger V_\mu = 1; \quad V_\mu = \frac{1 - \gamma_\mu T_\mu}{2} + \frac{1 + \gamma_\mu T_\mu^\dagger}{2}.
\]

In even \( d \) we associate to the Wilson Dirac operator the hermitian Wilson Dirac operator, \( H_W(m) = \gamma^{d+1} D_W(m) \).

All our lattices are assumed finite and therefore all our operators are finite dimensional matrices. An eigenvalue of a matrix \( A \) will be denoted by \( \lambda(A) \); if the eigenvalues are labeled, the label is attached to \( \lambda \). When it makes sense, we may deal with the maximal(minimal) eigenvalues of \( A \), \( \lambda_{\text{max(min)}}(A) \). We choose the following norm definition for matrices \( A \):

\[
\|A\| = \left[ \lambda_{\text{max}}(A^\dagger A) \right]^{\frac{1}{2}}.
\]

This is a standard choice, induced by the vector norm \( \|v\|^2 = \sum_I |v_I|^2 \), where \( I \) is a generic component index \([2]\). The norm of a gauge covariant matrix is gauge invariant.

**Formal Continuum Limit**

The connection to the continuum is as follows: Assume to be given smooth functions \( A_\mu(x) \) on the torus. Then,

\[
U_\mu(x) = \lim_{N \to \infty} \left[ e^{i \frac{\pi}{N} A_\mu(x)} e^{i \frac{\pi}{N} A_\mu(x + \frac{\pi}{N} \hat{\mu})} e^{i \frac{\pi}{N} A_\mu(x + 2 \frac{\pi}{N} \hat{\mu})} \ldots e^{i \frac{\pi}{N} A_\mu(x + (N-1) \frac{\pi}{N} \hat{\mu})} \right] \equiv P \exp[i \int dx_\mu A_\mu(x)] \quad \text{(the symbol P denotes “path ordering”).}
\]

Consider a smooth function \( \psi_c(x) \) with same index structure as the corresponding object on the lattice. By looking at \( x \)'s coinciding with a lattice point one gets a lattice vector \( \psi(x = \vec{n}a) \), where \( \vec{n} \in \mathbb{Z}^d \). The action of the \( T_\mu \) produces another lattice vector \( \psi' \). One can define a continuum operator, \( T_{\mu c} \) such that the lattice restriction of \( T_{\mu c} \psi_c \) will be a function \( \psi'_c \) whose lattice restriction is \( \psi' \). The formula is\( f_2 \):

\[
T_{\mu c} = e^{aD_\mu}, \quad D_\mu = \partial_\mu + iA_\mu.
\]

\( f_1 \) In general the \( A_\mu(x) \) aren’t smooth functions, rather they make up a one form \( \sum_\mu A_\mu(x) dx_\mu \) which is a smooth connection on a possibly nontrivial bundle with structure group \( SU(n) \) over the four-torus.

\( f_2 \) This generalizes an observation of van Baal \([3]\).
The simplicity of this expression can be viewed as a motivation to introduce the $T_{\mu}$’s as central objects on the lattice in the first place.

The formula is easy to prove:

$$\psi_c(x + a\hat{\mu}) = e^{a\partial_\mu} \psi_c(x),$$

for any vector $\psi_c$. On the other hand, for any operator $O_c$ acting pointwise by $O_c(x)$ we have:

$$O_c(x + b\hat{\mu}) = e^{b\partial_\mu} O_c(x) e^{-b\partial_\mu}.$$

Inserting this expression (with $b = k \frac{a}{N}$) repeatedly into the definition of $U_{\mu}(x)$, implementing the shift of the argument of $\psi_c(x)$ as above, and taking $N$ to infinity at the end, produces the desired result using Trotter’s formula [4].

The $V_{\mu}$’s have associated continuum operators $V_{\mu c}$, given by:

$$V_{\mu c} = e^{-a\gamma_\mu D_\mu} \quad \text{no sum on } \mu.$$ 

The Wilson Dirac operator is a lattice restriction of the continuum operator

$$aD_W(m) = m + \sum_\mu (1 - e^{-a\gamma_\mu D_\mu}).$$

$D_W(m)$ could be viewed as an approximation to $\gamma_\mu D_\mu$ in the continuum which is good for eigenvalues small in absolute value but whose spectrum is restricted to a bounded domain. Such operators are frequently introduced when one regulates infinities in the continuum. The continuum Dirac operator $\sum_\mu \gamma_\mu D_\mu$ formally emerges as $a$ goes to zero, and the mass is of order $\frac{m}{a}$, where $m$ is a pure number. But, as an operator in the continuum, $D_W(m)$ is special: when it acts on $\psi_c$ to produce $\psi'_c$, the values of $\psi'_c$ at lattice points are solely determined by values of $\psi_c$ at lattice points. Therefore, there exists an exact relation to the lattice operator $D_W(m)$.

There is no remnant of chiral symmetry (for even dimension $d$) because $D_W(m)$ isn’t just a function of $\sum_\mu \gamma_\mu D_\mu$; only in the small $a$ limit (strictly speaking, one would need to replace $m$ by $m_c a$ before taking $a$ to zero) do we get an expression involving only the chiral combination $\sum_\mu \gamma_\mu D_\mu$.

It is important to appreciate that one does not need $D_W(0)$ to anticommute with $\gamma_{d+1}$ to have some amount of lattice chirality: any reasonable $D_c(m)$ that is a function of only the combination $\sum_\mu \gamma_\mu D_\mu$ would do. For example, if $aD_W(m)$ were replaced by

$$aD'_W(m) = m + 1 - e\sum_\mu \gamma_\mu D_\mu,$$
we would have enough symmetry because
\[
\gamma_{d+1} e^{-\frac{1}{2} \sum_\mu \gamma_\mu D_\mu} \left[ e^\mu - e^{-\mu+\sum_\mu \gamma_\mu D_\mu} \right] e^{-\frac{1}{2} \sum_\mu \gamma_\mu D_\mu} \gamma_{d+1} = - \left[ e^{-\mu} - e^{\mu+\sum_\mu \gamma_\mu D_\mu} \right].
\]

Since \( \det e^{-\frac{1}{2} \sum_\mu \gamma_\mu D_\mu} \) is unity \( \frac{\partial}{\partial \mu} \log \det \left[ e^\mu - e^{-\mu+\sum_\mu \gamma_\mu D_\mu} \right] \) is odd in \( \mu \) and this is enough to eliminate additive quark mass renormalization. However, the operator \( e^{\sum_\mu \gamma_\mu D_\mu} \) cannot be restricted to the lattice because when it acts on \( \psi \) and produces \( \psi' \) it is not true that the values of \( \psi' \) at lattice points depend only on values of \( \psi \) at lattice points.

One can try to “improve” \( D_{Wc}(m) \) by looking at the difference \( D_{Wc}'(m) - D_{Wc}(m) \) to leading order in \( a \) and replacing it by a function of the \( T_{\mu\nu c} \) (again to leading order in \( a \)). Adding the new term to \( D_{Wc}(m) \) produces an operator which can be restricted to the lattice and is “clover improved”; it agrees with \( D_{Wc}'(m) \) to leading and subleading order in \( a \). In fluctuating gauge field backgrounds one changes the coefficient of the new term to a number determined numerically.

One can also maintain chiral symmetry on the lattice exactly [5][6], using the overlap Dirac operator.

**Upper bound**

Our first objective is to find a bound for the largest eigenvalue of \( H^2_W \). Clearly, \( \lambda_{\text{max}}(H^2_W) = \|D_W(m)\|^2 \). The triangle inequality then gives:
\[
\|D_W(m)\| \leq |m + d| + \sum_\mu \|V_\mu\| = |m + d| + d.
\]

The lowest upper bound as a function of mass is obtained at \( m = -d \), which is a symmetry point for \( H^2_W(m) \), because \( D_W(-d) \) and \( -D_W(-d) \) are unitarily equivalent. This is a consequence of the existence of a unitary hermitian operator \( S \) such that \( SV_\mu S = -V_\mu \), implying \( SD_W(m)S = -D_W(-m - 2d) \); \( S \) is diagonal and the diagonal entries are 1 if the site \( x \) has \( \sum_\mu x_\mu \) even and \(-1 \) otherwise. \( S \) exists because the hypercubic lattice we are working on is bipartite.

For \( m \geq -d \) the upper bound is attained iff there exists a vector \( \psi \) which is a common eigenvector to all \( dV_\mu \) operators, with the eigenvalue \(-1 \) in each case. It is likely to find such an eigenvector when \( [T_\mu, T_\nu] = 0 \) for all \( \mu \) and \( \nu \). These commutators vanish when all plaquette parallel transporters are unity; this is so, in particular, in the free case.

**Lower bound**
Let us introduce some shorthand notation:

\[ h_\mu = \frac{1}{2} (T_\mu + T_\mu^\dagger) = h_\mu^\dagger, \quad a_\mu = \frac{1}{2} \gamma_\mu (T_\mu^\dagger - T_\mu) = -a_\mu^\dagger. \]

The unitarity of \( V_\mu \) holds because of the identities

\[ h_\mu^2 - a_\mu^2 = 1, \quad [h_\mu, a_\mu] = 0. \]

Let \( \lambda(m) = \lambda(H_W(m)) \) be some eigenvalue of \( H_W(m) \). \( \lambda(m) \) is differentiable because \( H_W(m) \) depends smoothly on \( m \): \( \frac{d\lambda}{dm} = \sum x,i,\alpha,\beta \psi_i^\dagger(x) \gamma_5 \alpha,\beta \psi(x) \), where \( H_W(m)\psi = \lambda(m)\psi \) and \( \psi \) has unit norm. Since \( \gamma_5^2 = 1 \) one has

\[ \left| \frac{d\lambda}{dm} \right| \leq 1. \]

The theoretical usefulness of expressions for \( \frac{d\lambda}{dm} \) has been recently emphasized by Kerler [7]. This inequality restricts the slope of lines describing the flow of eigenvalues of \( H_W(m) \) as a function of \( m \). We shall refer to this inequality as the “flow inequality”. It has an important consequence that we shall prove below: If we know that \( 0 < \lambda_{\text{min}}(H^2_W(m)) \) for some \( m \), we have

\[ \left[ \lambda_{\text{min}}(H^2_W(m')) \right]^\frac{1}{2} \geq \left[ \lambda_{\text{min}}(H^2_W(m)) \right]^\frac{1}{2} - |m - m'|. \]

Before describing the proof let us note that the result is useful only if

\[ |m - m'| < \left[ \lambda_{\text{min}}(H^2_W(m)) \right]^\frac{1}{2}. \]

The main observation is that a lower bound on \( \left[ \lambda_{\text{min}}(H^2_W(m)) \right]^\frac{1}{2} \) at an arbitrary mass point \( m \) can be extended to a lower bound on \( \left[ \lambda_{\text{min}}(H^2_W(m')) \right]^\frac{1}{2} \) in some mass range around \( m \).

The basic inequality can be best proven appealing to a sketch shown in Figure 3: The graphical meaning of the inequality is that \( H^2_W(m) \) has no eigenvalues in the area bounded by the right angle rhombus in the figure when it is given that there are no eigenvalues along its main diagonal (\( A, B \)). Recognizing this, the proof becomes trivial: if we did have an eigenvalue anywhere inside the rhombus the flow inequality would have to be violated somewhere in order to avoid an eigenvalue flow crossing the main diagonal.
We start with an explicit formula for $H_W^2(m)$:

$$H_W^2(m) = \left[ m + \sum_{\mu} (1 - h_\mu) \right]^2 - \left[ \sum_{\mu} a_\mu \right]^2 - \sum_{\mu \neq \nu} [a_\mu, h_\nu] =$$

$$m^2 + 2(m+1) \sum_{\mu} (1 - h_\mu) + \sum_{\mu \neq \nu} [(1 - h_\mu)(1 - h_\nu) - a_\mu a_\nu - [a_\mu, h_\nu]].$$

While in the continuum $D^\dagger(m)D(m)$ commutes with $\gamma_{d+1}$ the last term in $H_W^2(m)$ does not. All terms are individually hermitian. Since $H_W(m)$ connected sites $x, x'$ with $|x - x'| = 0, 1$ we could have expected $H_W^2(m)$ to connect sites with $|x - x'| = 0, 1, \sqrt{2}, 2$, but because of the relations $h_\mu^2 - a_\mu^2 = 1$ and $[h_\mu, a_\mu] = 0$ sites with $|x - x'| = 2$ are still disconnected. Another special property of $H_W^2(m)$ is that the site diagonal piece is proportional to the identity matrix.

If $[T_\mu, T_\nu] = 0$ we have $\sum_{\mu \neq \nu} a_\mu a_\nu = 0$, $[h_\mu, a_\nu] = 0$ and $[h_\mu, h_\nu] = 0$. Then,

$$H_W^2(m) = m^2 + 2(m+1) \sum_{\mu} (1 - h_\mu) + \sum_{\mu \neq \nu} (1 - h_\mu)(1 - h_\nu).$$

If we keep all $h_\mu$ fixed but one, say $h_\nu$, the dependence on the latter is linear, so the extremal values are obtained at $h_\nu = \pm 1$. The argument is applied again and again to $h_\nu$.

---

\[ f_3 \] For two sites $x$ and $y$ we define $|x - y| = \sqrt{\sum_{\mu} (x_\mu - y_\mu)^2}$
a decreasing number of remaining directions leading to the conclusion that in order to find the extrema of $H_W^2$, viewed as a function of the quantities $h_\mu$ (more precisely, their eigenvalues, since the $h_\mu$ can be simultaneously diagonalized by assumption) we only need to check the $2^d$ possibilities $h_\mu = \pm 1$. The upper bound comes out as above, and the lower bound on $[\lambda_{\min}(H_W^2)]^{1/2}$ has the shape shown in the Figure 2. We learn that at the points $m = 0, -2, -4, \ldots -2d$ the theory has massless fermions; the multiplicities are given by $$d! (d-n)! n!$$ where $m = -2n$, $n=0,1,2,\ldots,d$. Thus, for $m = -2, -4, \ldots -2d+2$ we have several doublers, the number of different species being given by the number of different $h_\mu$ configurations producing a zero at the respective special mass point.

From now on we shall concentrate on the region $-2 < m < 0$. This region is interesting when we want to deal with one Dirac fermion and avoid doublers. The region close to $m = 0$ is important for traditional numerical QCD with Wilson fermions. The region close to $m = -1$ is important for applications of the overlap Dirac operator where one would like $H_W^2(m)$ to have a large gap around zero. When $[T_\mu, T_\nu] = 0$, the highest lower bound is obtained at $m = -1$. As long as all operators $[T_\mu, T_\nu]$ are small in norm we expect the same to be true. We therefore focus on the point $m = -1$ first, and later extend the bound to a range around $m = -1$ using the consequence of the flow inequality established earlier.

In the general case where the matrices $T_\mu$ do not commute, we have

$$H_W^2(-1) = 1 + \sum_{\mu \neq \nu} [(1 - h_\mu)(1 - h_\nu) - a_\mu a_\nu - [a_\mu, h_\nu]].$$

We now analyze each term in the bracket individually; we treat them separately because their spinorial index structures are different. The first term is rewritten as:

$$\sum_{\mu \neq \nu} [(1 - h_\mu)(1 - h_\nu)] = \frac{1}{4} \sum_{\mu \neq \nu} (1 - T_\mu)(1 - T_\mu^\dagger)(1 - T_\nu)(1 - T_\nu^\dagger) = Q + X.$$

Here, $Q$ is positive semidefinite,

$$Q = \frac{1}{8} \sum_{\mu \neq \nu} [(1 - T_\mu)(1 - T_\nu)[(1 - T_\mu)(1 - T_\nu)]^\dagger + (1 - T_\mu^\dagger)(1 - T_\nu)[(1 - T_\mu^\dagger)(1 - T_\nu)]^\dagger],$$

while $X$ depends only on $T_\mu$-commutators:

$$X = -\frac{1}{8} \sum_{\mu \neq \nu} (T_\mu [T_\mu^\dagger, T_\nu + T_\nu^\dagger] + T_\mu^\dagger [T_\mu, T_\nu + T_\nu^\dagger]) = -\frac{1}{8} \sum_{\mu} [T_\mu, \sum_\nu (T_\nu + T_\nu^\dagger)].$$

Proceeding, we find

$$-\sum_{\mu \neq \nu} a_\mu a_\nu = -\frac{1}{8} \sum_{\mu \neq \nu} \gamma_\mu \gamma_\nu [T_\mu - T_\mu^\dagger, T_\nu - T_\nu^\dagger] = Y,$$
and

\[ -\sum_{\mu \neq \nu}[a_\mu, h_\nu] = \frac{1}{8} \sum_{\mu \neq \nu}[(\gamma_\mu - \gamma_\nu)([T_\mu, T_\nu] + h.c.) + (\gamma_\mu + \gamma_\nu)([T_\mu, T_\nu]^\dagger + h.c.)] = Z. \]

The operators \( Q, X, Y, Z \) are all hermitian. Moreover, each of the traces of \( X^2, Y^2, Z^2 \) are linearly related to the single plaquette Wilson action (see below) and decrease when the latter increases and the continuum limit is approached.

Consider now the commutators \([T_\mu, T_\nu] \). Their norm is determined by:

\[ [T_\mu, T_\nu]^\dagger[T_\mu, T_\nu] = (1 - P_{\mu\nu})^\dagger(1 - P_{\mu\nu}), \]

where the unitary \( P_{\mu\nu} \) are given by:

\[ P_{\mu\nu} = T_\nu^\dagger T_\mu^\dagger T_\nu T_\mu. \]

The operators \( P_{\mu\nu} \) are site diagonal, with entries that are parallel transporters round plaquettes:

\[ (P_{\mu\nu}\psi)(x) = U_{\mu\nu}(x)\psi(x), \quad U_{\mu\nu}(x) = U_{\nu}^\dagger(x-\hat{\nu})U_{\mu}^\dagger(x-\hat{\nu}-\hat{\mu})U_{\nu}(x-\hat{\nu}-\hat{\mu})U_{\mu}(x-\hat{\mu}). \]

\( U_{\mu\nu}(x) \) is associated with the elementary loop starting at site \( x \), going first in the negative \( \nu \) direction, then in the negative \( \mu \) direction, and coming back round the plaquette.

The main relation is:

\[ \| [T_\mu, T_\nu] \| = \| 1 - P_{\mu\nu} \|. \]

Any pure gauge action with the right continuum limit will strongly prefer configurations where all \( U_{\mu\nu}(x) \) are close to unit matrix. Therefore, it is not unreasonable to impose the constraint, for all \( \mu > \nu \),

\[ \| [T_\mu, T_\nu] \| \leq \epsilon_{\mu\nu}. \]

Note that this is equivalent to

\[ \| 1 - U_{\mu\nu}(x) \| \leq \epsilon_{\mu\nu} \]

for every site \( x \). It is easy to see that the same bound will hold when we interchange in the commutator the \( \mu, \nu \) indices, and when we replace, independently, the \( T_\mu \) and \( T_\nu \) operators by their hermitian conjugates.

Using the triangle inequality and that \( \| AB \| \leq \| A \| \| B \| \), we now obtain:

\[ \| X \| \leq \sum_{\mu > \nu} \epsilon_{\mu\nu}, \quad \| Y \| \leq \sum_{\mu > \nu} \epsilon_{\mu\nu}, \quad \| Z \| \leq \sqrt{2} \sum_{\mu > \nu} \epsilon_{\mu\nu}. \]
The $\sqrt{2}$ factor comes in because $(\gamma_\mu \pm \gamma_\nu)^2 = 2$ for $\mu \neq \nu$. We finally obtain:

$$\lambda_{\min}(X) \geq -\sum_{\mu>\nu} \epsilon_{\mu\nu}, \quad \lambda_{\min}(Y) \geq -\sum_{\mu>\nu} \epsilon_{\mu\nu}, \quad \lambda_{\min}(Z) \geq -\sqrt{2} \sum_{\mu>\nu} \epsilon_{\mu\nu}.$$ 

By the variational principle and the positivity of $Q$ we arrive at:

$$\lambda_{\min}(H^2(-1)) \geq 1 - (2 + \sqrt{2}) \sum_{\mu>\nu} \epsilon_{\mu\nu}.$$ 

Our result is meaningful only when the number on the right hand side in the above equation is non-negative.

In the rotational invariant case one could set $\epsilon_{\mu\nu} = \eta$. Then, for $d = 4$, we obtain

$$\sqrt{\lambda_{\min}(H^2(-1))} \geq \sqrt{1 - 6(2 + \sqrt{2})\eta} \approx \sqrt{1 - 20.5\eta}.$$ 

The general bound we obtained is:

$$\left[ \lambda_{\min}(D_W^\dagger(m)D_W(m)) \right]^\frac{1}{2} \geq \left[ 1 - (2 + \sqrt{2}) \sum_{\mu>\nu} \epsilon_{\mu\nu} \right]^\frac{1}{2} - |1 + m|.$$ 

This bound is useful only for

$$|1 + m| \leq \left[ 1 - (2 + \sqrt{2}) \sum_{\mu>\nu} \epsilon_{\mu\nu} \right]^\frac{1}{2}.$$ 

This range is contained in the open segment $-2 < m < 0$. The bound holds in both even and odd dimensions. In the particular case of domain wall fermions, plaquettes parallel to the extra dimension make no contribution since their $\epsilon_{\mu\nu}$ vanishes.

**Comparison to other work**

Related issues were studied in [8] and in [9]. The authors of [8] established the upper bound

$$\sqrt{\lambda_{\max}(H_W^2(m))} \leq 8.$$ 

in four dimensions with the restriction $-2 < m < 0$. This is compatible, but less stringent than our upper bound, which becomes $m + 8$ in this mass range.

In numerical investigations with pure gauge Wilson action, it was reported in [8] that, for $\beta = 6.0, 6.2, 6.4$ and $m = -1.0, -1.2, -1.4, -1.6,$ for $SU(3)$, $\lambda_{\max}(H_W^2(m))$ stays around
$4^1$ and hardly changes. Our upper bound for $m = -1.6$ is $6.4^2 = 40.96$ and increases for
the lower $m$‘s. Thus, at the extremal mass value (assuming the value quoted in [8] was
rounded), our bound is saturated to numerical accuracy. The claimed mass independence
seems surprising, and not entirely consistent with numerical results at other $\beta$ values and
volume sizes $f^4$.

In [8] a bound on $\lambda_{\text{min}}(H_W^2(-1))$ is also established. It is expressed in terms of a
bound on the norm of the commutators, but the precise definition of the norm used is not
given. I shall assume it is the one adopted in this paper. A bound is quoted only for the
d = 4 case, for $m = -1f^5$ and for the rotational invariant case $\epsilon_{\mu\nu} = \eta$. The bound derived
in [8] is:

$$\lambda_{\text{min}}(H_W^2(-1)) > 1 - 30\eta.$$  

This bound is compatible with the result of this paper, $\lambda_{\text{min}}(H_W^2(-1)) \geq [1 - 6(2 + \sqrt{2})\eta]$, but weaker. To be sure that $H_W^2(-1)$ has no zero eigenvalues the bound in [8] places a
restriction on $\eta$ that is stronger than ours by about one third.

Lessons

Let us first identify what about our results could have been expected without any
calculations. Clearly, we know that there will be some uniform upper bounds on the
spectrum just by virtue of compactifying momentum space and because the $U_\mu(x)$‘s are
unitary. Moreover, once the free case is worked out and the spectral restrictions of Figure 2
are derived, one knows that close to the continuum the structure will be essentially similar
even in the presence of nontrivial gauge fields. The reasoning is as follows: We are dealing
with operators that are analytic in $T_\mu$ and Figure 2 holds whenever all $T_\mu$‘s commute. All
that enters in the bound derivations above is that the $T_\mu$‘s are unitary. Commuting unitary
$T_\mu$‘s can be smoothly deformed into non-commuting ones and the changes in the spectrum
must be smooth too. Thus, if the commutators of the $T_\mu$‘s are sufficiently small there will
be a region around $m = -1$ where the spectrum of $H_W(m)$ will have a gap around zero.
One can simply think about the commuting case as a “semiclassical” approximation to the
non-commuting case.

---

$f^4$ The numerical work was carried out by the SCRI group, at the time consisting of
Edwards, Heller and Narayanan.  

$f^5$ According to David Adams [9], in unpublished work, the authors of [8] have extended
their bound by using the triangle inequality to a range of $m$ values contained within the
segment ($-2, 0$).
The operators $T_\mu$ connect only sites one spacing apart in the $\mu$-direction. The gauge invariant norm of the $T_\mu$ commutators cannot depend on anything else but the norm of the elementary plaquettes. Forcing all unitary plaquette operators close to identity produces a link configuration for which the $T_\mu$’s almost commute. The precise relation between the $T_\mu$-commutators and the plaquettes is well known [10] since the discovery of large $n$ reduction of lattice gauge theories [11].

So, all that really required some work was to turn the above into a quantitative estimate. Because of the practical difficulties associated with low eigenvalues of $H_W^2(m)$ it makes sense to try to be as careful as possible in deriving the quantitative form of the bounds. Still, it is known that the lower bounds in the $-2 < m < 0$ region are not directly useful in backgrounds generated at coupling constants that are practical in numerical QCD today. In spite of this, the exact bounds and their derivation might provide helpful insights, in particular in the context of implementations of the overlap Dirac operator. In this case one wishes to work with operators $H_W(m)$ with $-2 < m < 0$ but with as large a gap around zero as possible. This would make the matrix $H_W(m)$ well conditioned and speed up the calculations.

The most basic observation is that one can control the gap in $H_W(m)$ by controlling the plaquette variables alone$^{f6}$. This was understood long ago [13]; a natural guess would be that replacing the pure Wilson gauge action by the so called “positive plaquette” model [14] (for gauge group $SU(2)$) will create a gap around zero. Numerical checks by Urs Heller in early 1998 have shown that this was not the case [15]. In addition, one cannot just change the form of a single plaquette action and get something useful in four dimensions. The correlation length increases exponentially as the plaquettes are forced to identity and physical realistic volumes rapidly become totally impractical. A milder approach is therefore called for. There are a few possibilities.

First, one could use a more complicated action then a single plaquette one. The idea is that a more complicated action might make the plaquettes close to unity, but still keep the gauge fields sufficiently random so that the correlation length does not exceed a few lattice spacings. The improvements observed in simulations using domain walls (which can be viewed as a particular truncation of the overlap [16]) when one switches from Wilson to so called “Iwasaki actions” might be a reflection of this mechanism [17]. A more systematic approach would be to follow an approximate renormalization group trajectory [18], where the correlation length is controlled, to regimes in the coupling constant space where the

$^{f6}$ This was exploited when the parameters of the first dynamical simulation of the exactly massless Schwinger model were chosen [12].
single plaquettes are closer to unity. A note of caution: the inclusion of the fermionic determinant in the gauge measure may be important and a fix that works for quenched simulations may fail in the dynamical case [19].

Another observation is that making only the plaquettes in some directions close to unity would help. This only requires to increase one dimension of the lattice and there is no exponential relation between this dimension and the closeness of the time-like plaquettes to unity. In four dimensions there are other good reasons for working on asymmetric lattices [20], so this looks like a cheap and attractive alternative worth exploring\textsuperscript{f7}. In lower dimensions than four the impact of going to asymmetric lattices would be even more pronounced.

Yet another possibility is to filter out the “roughness” from the gauge background seen by the fermions by replacing the link variables $U_\mu(x)$ by new link variables $U_\mu^{\text{APE}}(x)$ which are functions of the original link variables, transform the same way under gauge transformations, but produce plaquette variables closer to unity. Recent work has obtained such “APE smeared” $U_\mu^{\text{APE}}(x)$ [21] with associated plaquettes extremely close to unity [22]. Of course too much “filtering” may take the lattice theory at typical simulation parameters too far away from the desired continuum limit of QCD\textsuperscript{f8}. If this is true, one could also try a “half smeared” approach where only the links entering the “Wilson mass term” $\frac{1}{2} \sum_\mu (T_\mu + T_\mu^\dagger)$ in $D_W(m)$ are APE smeared but the links entering the chiral part $\frac{1}{2} \sum_\mu \gamma_\mu (T_\mu - T_\mu^\dagger)$ are not, so the fermions are not insulated from the ultraviolet fluctuations in the gauge field. Unfortunately this would spoil the relations $h_\mu^2 - a_\mu^2 = 1$ and $[h_\mu, a_\mu] = 0$, so the consequences on the bounds are complicated. Also, the spinorial structure no longer only involves the projectors $\frac{1}{2} (1 \pm \gamma_\mu)$ which causes some numerical overhead. Note however that with APE smearing the difference between $U_\mu^{\text{APE}}(x)$ and $U_\mu(x)$ goes to zero when the original $T_\mu$ commutators go to zero. Therefore, some bounds of similar structure to the bounds presented here would still hold.

It is hoped that the analysis of this paper would prove helpful in guiding our search for improvements in the gauge action and in the structure of $D_W(m)$.

Acknowledgments

My research at Rutgers is partially supported by the DOE under grant \# DE-FG05-

\textsuperscript{f7} K.-F. Liu has informed me already in September that his group is studying some physics questions using the overlap on asymmetric lattices.

\textsuperscript{f8} Too little filtering may provide no advantages: for example, in a dynamical simulation of a two dimensional chiral model [23], modest filtering produced no gains.
I wish to thank David Adams for exchanges regarding the lower bounds. I am indebted to Urs Heller for providing numerical information on the spectrum of the Wilson Dirac Hamiltonian in gauge fields generated both with the positive plaquette action and with the Wilson action. I am grateful to Rajamani Narayanan for making available to me numerical results about eigenvalue flows and about upper bounds on $H_W(m)$.
