ABSTRACT

Joint optimization of multi-channel front-end and automatic speech recognition (ASR) has attracted much interest. While promising results have been reported for various tasks, past studies on its meeting transcription application were limited to small scale experiments. It is still unclear whether such a joint framework can be beneficial for a more practical setup where a massive amount of single channel training data can be leveraged for building a strong ASR back-end. In this work, we present our investigation on the joint modeling of a mask-based beamformer and Attention-Encoder-Decoder-based ASR in the setting where we have 75k hours of single-channel data and a relatively small amount of real multi-channel data for model training. We explore effective training procedures, including a comparison of simulated and real multi-channel training data. To guide the recognition towards a target speaker and deal with overlapped speech, we also explore various combinations of bias information, such as direction of arrivals and speaker profiles. We propose an effective location bias integration method called deep concatenation for the beamformer network. In our evaluation on various meeting recordings, we show that the proposed framework achieves a substantial word error rate reduction.

Index Terms— Meeting transcription, end-to-end multi-channel ASR, target-speaker ASR, bias information

1. INTRODUCTION

Meeting transcription with speaker annotation is one of the challenging tasks in automatic speech recognition (ASR) field [1][2][3]. It is difficult not only because of its natural conversational content but also because of complicated acoustic conditions often with speaker overlaps [4][5][6]. To improve the model robustness in challenging acoustic conditions, multi-channel front-end speech processing is often introduced to separate target speaker signals from the background noise, reverberation and interfering speakers [2].

One of the common approaches for ASR front-end processing is time-frequency mask-based beamforming by using a mask estimation network [7][8][9][10][11][12]. It has shown promising results in various ASR benchmarks, such as AMI [13] and CHiME challenges [14][15][16]. However, the mask estimation network is normally trained by using simulation data in order to prepare an accurate reference mask, leading to potential mismatch problems for real data. Furthermore, the network is often trained by optimizing a signal-level criterion, which is not necessarily optimal for ASR.

Recent studies suggest that joint optimization of multi-channel front-end and ASR can yield better recognition results than sequential processing scheme with separately optimized front-end and ASR modules [17][18][19][20][21][22]. With the joint optimization approach, all modules are connected in one computational graph and trained by back-propagating the ASR training loss to ensure optimal ASR performance (for the training set). The joint optimization also enables us to leverage transcribed real data for which reference clean signals are unavailable. This is advantageous for large scale training, as the signal level reference is usually extremely difficult to collect for real data compared with transcription. It would also help reduce the mismatch of training and testing conditions.

While the joint optimization approach is promising, previous studies on meeting (or more broadly conversation) transcription were either all conducted on simulated [21], small-scale data [14][18][20], or did not particularly emphasize the capability to deal with overlapped speech [4][25]. This is because acquiring accurate transcription for multi-channel meeting recordings is much more difficult than doing so for voice commands or other single-speaker dictation tasks. On the other hand, it is relatively easy to collect single-channel audio as the ASR training data. Therefore, it is practically important to explore the joint front-end and back-end modeling with a massive amount of single-channel training data and a limited amount of multi-channel training data. However, to the best of our knowledge, there has still been no exploration in this direction, especially with a scale of 75k hours of training data as is done in this paper.

Besides the joint modeling of front-end and back-end, due to the long recording nature in meetings, it is feasible for meeting transcription systems to leverage long context information that would help extract a target speech from overlapped sentences [2]. For instance, the direction of arrival (DOA) information can be encoded as angle features to get time-frequency masks that are biased toward the target speaker direction to reconstruct the target signal from the mixture [25]. The speaker embeddings could also be utilized to make the mask estimator biased to the target speaker [20][27][28]. Compared with the blind separation approach, target speech recognition does not have the permutation problem and thus could potentially lead to better result.

In this work, we describe our investigation on the effectiveness of an end-to-end multi-channel ASR (E2E MCASR) for meeting transcription under the condition that we leverage a massive amount of single-channel data for the back-end training while the multi-channel training data is still limited. The front-end and back-end models are then jointly optimized, which takes a multi-channel signal as input and outputs the word sequence of a target speech. We firstly review several key techniques, including mask-based beamforming, the usage of multi-channel features, Attention-Encoder-Decoder (AED)-based ASR, and joint training of these models. We then introduce bias information in the front-end module to further enhance the joint models for meeting transcription. We also explore a session-based semi-blind decoding strategy in which the bias information can be accurately estimated, where the SSL and speaker profile extraction can be simply replaced by online approaches. In our evaluation on various meeting recordings, we show that the proposed framework achieves substantial word error rate reduction.
2. E2E MCASR Frameowrk

Figure 1 shows how we leverage the E2E MCASR framework for the meeting transcription task. The framework consists of several modules.

2.1. Front-end module

2.1.1. Neural Beamforming

The neural beamformer is defined with parameter \( \theta_d \) as follows:

\[
O = \text{Beamformer}(X; \theta_d),
\]

where \( O \) and \( X \) denote the beamformed and noisy short-time Fourier transform (STFT) of signals for all frames and frequency bins, respectively. For beamforming, which converts the multi-channel signals \( x(t, f) \in X \) (\( t, f \) are time and frequency bin indexes, respectively) to single-channel beamformed signal \( o(t, f) \in O \)

\[
o(t, f) = w_{\text{MVDR}}^H(f)x(t, f),
\]

time-invariant minimum variance distortionless response (MVDR) beamformer \( w_{\text{MVDR}}(f) \) in the frequency domain has been employed. Mathematically, the MVDR filter can be calculated with the following formula

\[
w_{\text{MVDR}}(f) = \Phi_N^{-1}(f)\Phi_N(f)\Phi_S^{-1}(f)\mathbf{u},
\]

where \( \mathbf{u} \in \{0, 1\}^M \) is a one-hot vector to choose a reference microphone [29]. \( \text{Tr}() \) denotes the trace operation. \( \Phi_N(f) \) and \( \Phi_S(f) \) denote the power spectral density (PSD) matrices of noise and speech at frequency bin \( f \), respectively, which are calculated by

\[
\Phi_v(f) = \sum_{t=1}^{T} M_v(t, f)d^H(t, f)d(t, f) \quad \text{where} \quad v \in \{S, N\}
\]

Speech mask \( M_S(t, f) \in [0, 1] \) and noise mask \( M_N(t, f) \in [0, 1] \) are estimated by applying a bidirectional long short-term memory (BLSTM)-based network to each microphone. The masks are then averaged over the microphone channels for PSDs estimation. Note that a two-head (speech head and noise head) training scheme has been employed [8][9], where both speech masks and noise masks are estimated. The respective masks indicate the time-frequency bins that are dominated by speech and noise. The advantage of the two-head training scheme is that the BLSTM network has been given additional hints for better learning the relationship between the speech mask and noise mask, potentially leading to better mask predictions.

2.1.2. Unbiased multi-channel features

Multi-channel features have been shown effective for the front-end network. In [19] [21] [22], the spectrum of \( M \)-channel signals were fed into the mask estimation network (referred to as STFT features in this work). In [6][20], the authors utilized inter-microphone phase difference (IPD) features to capture the spatial pattern from a multi-channel input, and observed a significant performance boost in both speech separation and recognition tasks. The IPD features can be calculated by

\[
\text{IPD}_i(t, f) = \angle \frac{x_i(t, f)}{x_1(t, f)} \quad i = 2, ..., M,
\]

where \( \angle \) outputs angle of the input argument, \( M \) denotes the number of the microphones, \( i \) is the microphone index. Utterance-wise normalization [20] is applied before the IPD features are concatenated with the STFT features. Unlike the work of [20], we concatenate the IPD features calculated with respect to the first microphone to the STFT of each channel, which are fed to the mask estimation network. This results in multiple mask estimates, which are then averaged across the channels.

2.2. Joint front-end and ASR via feature transformation layer

In the joint front-end and back-end training scheme, the signal is processed by the front-end and back-end layers sequentially, where a feature transformation layer is applied that maps the beamformed output from front-end layers to log mel filterbanks. Considering that back-end ASR usually takes multiple contextual frames as the input, the frame-based STFT feature is stacked in the feature transformation layer as follows,

\[
O_P = \text{Frame2Superframe}(\text{LogMel}([O]), P),
\]
where $P$ is the number of frames to be stacked. Finally, global mean-variance normalization (GMVN) is applied on top of the stacked filterbank features $O_P$ to derive the input $\hat{O} = \{o_1, ..., o_T\}$ for back-end ASR, which is

$$\hat{O} = \text{GMVN}(O_P),$$

where the mean and variance vectors are obtained from the single-channel data for back-end training rather than the multi-channel training data.

We select to combine the front-end and back-end via the feature transformation layer in order to fully utilize both single-channel and multi-channel training data. The details of the training scheme will be explained in Section 4.4.

### 2.3. AED-based ASR

The AED-based ASR consists of encoder, attention, and decoder modules. The AED model follows three steps to generate text sequence $Y = \{y_1, ..., y_T\}$ given acoustic feature $\hat{O} = \{o_1, ..., o_T\}$.

Firstly, the encoder module converts the input sequence $\hat{O}$ into a sequence of embeddings $H^{enc}$.

$$H^{enc} = \{h_1^{enc}, ..., h_T^{enc}\} = \text{Encoder}(\hat{O}).$$

Then, for every decoder step $n$, the attention module outputs context vector $c_n$ with attention weight $\alpha_n$, given decoder state vector $q_n$, the previous attention weight $\alpha_{n-1}$, and $H^{enc}$ as follows,

$$c_n, \alpha_n = \text{Attention}(q_n, \alpha_{n-1}, H^{enc}).$$

Finally, the output distribution $y_n$ is estimated given the context vector $c_n$ and the decoder state vector $q_n$ as follows,

$$q_n = \text{DecoderRNN}(y_{n-1}, c_{n-1}, q_{n-1}),$$

$$y_n = \text{DecoderOut}(c_n, q_n).$$

The DecoderRNN consists of several RNN layers and an affine transformation followed by a softmax output layer are used for DecoderOut. The model is trained to minimize the cross entropy loss between $Y$ and reference label $R = \{r_1, ..., r_T\}$ as follows

$$L^{CE} = \sum_{n=1}^{N+1} \text{CE}(y_n, r_n),$$

where $\text{CE}(\cdot)$ denotes the cross entropy function, $N$ is the number of symbols in the reference $R$, and $\langle \text{eos} \rangle$ is the special symbol indicating the end of a sentence.

### 3. E2E MCASR WITH TARGET BIAS INFORMATION

The bias information, such as locations of attendees in the meeting [26] and attendees’ profiles [20, 30], guides the framework towards target speech recognition, and is shown effective in both separation and recognition task. We incorporate the additional information for each target speaker to further improve the E2E MCASR system in this work. In meeting scenario, both location and speaker bias can be formed by averaging statistics from long recording with the help of diarization algorithms. For example, from the diarization system [2], we can robustly identify the active region for each speaker, from which we can roughly estimate the location and speaker embedding by the sound source localization and speaker identification systems, under the assumption that the speakers don’t move frequently during the meeting.

### 3.1. Location bias in model training

#### 3.1.1. Angle feature

We use angle feature [26] as spatial bias in this work. The angle feature is calculated by the cosine distance between the steering vector that derived from DOA [31] and the complex spectrum of each channel that is normalized by the first microphone or the IPD on all selected microphone pairs, as suggested in Eqn. [13].

$$A(t, f) = \frac{e_i(f) \hat{a}(t, f) / \|e_i(f)\|_2}{|e_i(f)|^2 / |\hat{a}(t, f)|^2}, \, i = 2, ..., M,$$

where $e_i(f)$ is the steering vector for target speaker at microphone $i$ and frequency $f$.

The target DOA for angle feature extraction is estimated by using the maximum likelihood sound source localization algorithm [32] with a 3° resolution.

During testing, following [26], an additional pre-masking step is applied in the decoding stage to increase the discrimination resolution between the target speaker and the others in the same meeting session. This step has one more assumption that the DOAs from all the other attendees are known. In this work, we use the session-based DOA estimation for each speaker. Then the pre-masking is applied to angle feature which is obtained using the target DOA. The new angle feature $A_t, f$ used for decoding is

$$A(t, f) = A(t, f) \ast \text{Relu}(|\text{Sign}(A(t, f) - A^u(t, f))|),$$

where the $\text{Relu}(|\text{Sign}(\cdot)|)$ function outputs 0 if the input is negative and 1 otherwise. $A^u$ is angle features derived from the other speakers with different locations. Eqn. [14] means the time-frequency bins dominated by other speakers are set to zero, motivated by the sparsity property of speech spectrogram. Here, we restrict $|\text{DOA}(A) - \text{DOA}(A^u)| > \theta$, which means we only remove the bins that are dominated by the speakers whose directions with respect to the target speaker are larger than angle $\theta$. Empirically, we set it to 30° (overall 360°) in the meeting transcription experiments.

### 3.2. Speaker bias in model training

The speaker information is also used as a biased feature for E2E MCASR in this work. However, compared to location information that all the directions can be covered in the training set, the speakers in testing phase may be unseen, e.g. the attendee does not have profiles or was not invited to the meeting.

A d-vector extractor trained on VoxCeleb Corpus [33, 34] is employed in this work [25]. A 128-dim d-vector is extracted from the first channel of the multi-channel audios and concatenated with each channel’s input features of the mask estimation network, illustrated by Fig[1(b)]. The d-vector extractor is a universal auxiliary network that provides additional speaker information for learning the masks of target speech. The reason that we use d-vector is because accurate speaker profiles or speaker anchors [20, 27] are not always available in the real meetings.

### 3.3. Deep concatenation

Indicated by Fig[1(b)], we can concatenate the input of the mask estimation network with the same angle feature/d-vector, where the operation is similar to the IPD feature. Alternatively, the bias feature can be concatenated to the embedding, which is the output of
the first layer of the mask estimation network. We name it deep concatenation in this work and refer to regular feature concatenation as shallow concatenation. It is inspired by the SpeakerBeam work that allows tracking speech from a target speaker using a speaker adaptation layer [27][30]. Simply using the biased feature at the input level realizes the bias at the input layer, while the input layer bias can be eliminated because the input layer also has to encode the other features, e.g. unbiased IPD feature, which is insufficient to guide the network to focus on the target speech. This operation is simple yet effective for target speech recognition, especially in the overlapped regions.

3.4. Session-based bias estimation
Transcribing the speeches of the target speaker can be successfully achieved by knowing the DOA and d-vector in advance. Due to that, the joint model is designed for offline meeting transcription, session-based bias information is valuable in this case. Given the ground-truth diarization, we use the longest non-overlapped segment in a specific meeting session to extract the DOA and d-vector for each speaker, then apply this bias information to all the segments in the same session. An implicit assumption is that all the speakers in the session are not moving frequently, which is usually the case in real meetings. The reason we would like to use this information is to simplify the procedures in decoding and evaluate how the E2E MCASR performs given the almost accurate bias information. In a meeting scenario, both the DOA and d-vector of the target speaker can be tracked online via diarization or auxiliary cameras [2].

4. MEETING TRANSCRIPTION EXPERIMENT

4.1. Single-channel training data for AED-based back-end
The training set for the AED-based model is 75 thousand (K) hours of single-channel transcribed data, recorded in various conditions. Both close-talking and far-field data were included in this training set, hence it also included non-meeting data.

4.2. Multi-channel training data
We used 165 sessions of real meeting data to train the front-end module. The meetings were recorded by using a 7-channel circular microphone array with one microphone in the center, as well as attendee-wise head-worn close-talking microphones. Hence, we were able to obtain two training sets with the same speech content - a real multi-channel set and a multi-channel set simulated from single-channel close-talking data. Note that the 60-hour close-talking segments were also included in 75K data for AED training. Information of these training sets is summarized in Table 1.

4.2.1. Real meeting data
Considering the fact that even humans sometimes find it difficult to accurately transcribe overlapped speech in meeting recordings, the data (60 hours, denoted by Real) we used for training only contained non-overlapped regions, which provided us with accurately segmented and labeled multi-channel audio data. Furthermore, to support the purpose of overlapped speech extraction, we generated another 60-hour overlapped data (denoted by Real+) on top of the non-overlapped one. Specifically, we classified the segments according to the speaker labels in each meeting session at first. Given each segment, we randomly chose an interference segment from another speaker in the same session, then got a random overlap ratio (1-100%) and trimmed this segment based on the interference duration, calculated by the overlap ratio and length of the segment to be mixed. Finally, we simply added this trimmed multi-channel interference signal to the segment to be mixed.

In this way, we manually generated another 60-hour overlapped data, while keeping the original transcription for each segment. The only assumption for this overlapped set is the voices’ images from different speakers at the microphone array position are additive. It is much closer to what the real overlapped speech would be like than purely simulated multi-channel signals which we will describe in the following section.

4.2.2. Simulated meeting data
Given the close-talking utterances with meeting session ids as well as the corresponding speaker label, we also created 60 hours of simulated multi-channel audio (denoted by Simu) for training as with the previous studies [20][27]. We tried to imitate the property of the multi-channel meeting recordings to the extent possible. Our simulation procedure was as follows,

1. For each meeting session (165 sessions in total), we counted the number of speakers;
2. We then randomly set the room size, length×width×height, within [4, 10]m×[4, 10]m×[2, 5]m and the reverberation time, RT60, between 0.15ms and 0.60ms;
3. Assuming all the speakers did not move during the session, we randomly picked a point to put the 7-channel microphone array (with the same geometry as the real recording device) at a [1.0, 1.5]m height. We also randomly determined the speakers’ positions under the constraint that the speaker-to-array distance was 1.0m or greater;
4. The room impulse responses (RIR) between the speakers and the microphone array were derived with the image method [36] and then applied to the corresponding speakers’ close-talking segments;
5. 7-channel diffuse noise signals were added to the reverberated sounds with a signal-to-noise ratio (SNR) between -5dB to 10dB. Finally, the simulated 7-channel signals were normalized to a certain volume.

4.3. Evaluation data
We evaluated the proposed method on 31 real meeting recordings, the statistics of which are presented in Table 1. According to the

---

Table 1. Training and evaluation data used for our meeting transcription experiments.

| Training set       | Evaluation Set 1 (Eval 1)     | Evaluation Set 2 (Eval 2)     |
|--------------------|--------------------------------|--------------------------------|
| Num. of Sessions   | 9 real meetings                | 22 real meetings               |
| Overlap condition  | 28,690 / 8,041 words           | 46,744 / 69,200 words         |
| Speakers           | 4-17 attendees, unseen in training | 3-15 attendees, no restriction on the seen/unseen assumption |

Training set:
- for Back-end: 75K hours, single-channel
- for Joint Model:
  - Simu: 60 hours, 7-channel, simulation, non-overlapped
  - Real: 60 hours, 7-channel, real, non-overlapped
  - Real+: 60 hours, 7-channel, generated by mixing Real
recording conditions, they were divided into Eval 1 and Eval 2, which contains the recordings of 9 sessions and 22 sessions, respectively. We used the reference start and end time of each utterance to extract evaluation segments, and each segment was categorized to either a non-overlapped or overlapped segment based on the absence or presence of speech of interference speakers. Note that we used the reference start and end time for our evaluation in order to evaluate the effectiveness of joint modeling without being affected by segmentation errors. In actual applications, segmentation will be done by using speaker diarization [2].

The non-overlap/overlap distribution of Eval 1 is similar to the validation set we used to train the front-end module and the speakers in Eval 1 were unseen in the 60-hour training set. However, we did not have such speaker unseen restrictions for Eval 2 (more common in real applications), though the overlap ratio of which is higher than Eval 1. Before decoding, we applied weighted prediction error (WPE) [37] to dereverberate the multi-channel signals.

4.4. Model architecture and training procedure

Given that the size of the multi-channel training data is much smaller than that of the single-channel data, we applied a two-step training strategy. In stage-1, we used the 75k-hour of single-channel data to train only the AED-based back-end; then in stage-2, the front-end module was appended to the network, and the parameters of the front-end module were updated by using the multi-channel data. The configurations of each module and training parameters are as follows.

4.4.1. Stage-1: Training AED-based back-end

The AED consisted of 6 layers of 1024-dim bi-directional gated recurrent unit (GRU). Layer normalization was applied between the GRU layers. The decoder had 2 layers of 1024-dim uni-directional GRU. A conventional location-aware content-based attention with a GRU layers. The decoder had 2 layers of 1024-dim uni-directional

4.4.2. Stage-2: Jointly training the front-end

The front-end module, specifically the mask estimation network, consisted of 2 BLSTM layers with each layer having 300 units. The front-end module was concatenated with the AED-based back-end via the feature transformation module which mapped the 257-dimension beamformer output to the 240-dimension log mel filterbanks. The input feature of the baseline front-end module was 257-dimension Short-time Fourier transform (STFT) of the multi-channel audios, concatenated with the IPD features which were calculated based on the microphone pairs $^\dagger$ (1, 0), (2, 0), (3, 0), (4, 0), (5, 0), (6, 0)] - center microphone was used as the reference for the

4.5. Simulated vs. real multi-channel training data

Table 3 shows the WER(%), comparisons using simulated or real data for front-end training.

Table 2. Baseline and WER(%) comparisons using simulated or real data for front-end training.

| System                  | Training Data | Feature         | Non-overlap | Overlap | Overall |
|-------------------------|---------------|-----------------|-------------|---------|---------|
| (Eval 1)                |               |                 |             |         |         |
| AED-ASR 75K             | FBANK         | 17.79           | 34.37       | 21.42   |         |

| E2E-MCASR 75K & Real    | 7-ch STFT     | 13.99           | 25.23       | 20.70   |         |
| E2E-MCASR 75K & Real    | + IPD         | 14.04           | 24.58       | 20.31   |         |

| Total data size (h) | Ratio (%) of overlapped segments | Eval 1 | Eval 2 |
|---------------------|----------------------------------|--------|--------|
|                     | NO / OL / All                    |        |        |
| 60                  | 0                                | 14.41 / 24.95 / 16.72 | 14.04 / 24.58 / 20.31 |
| 60                  | 30                               | 14.36 / 23.45 / 16.35 | 14.17 / 23.90 / 19.98 |
| 60                  | 60                               | 14.44 / 22.59 / 16.22 | 14.17 / 23.76 / 19.90 |
| 60                  | 100†                             | 14.17 / 22.48 / 15.99 | 14.26 / 23.95 / 20.04 |
| 120                 | 50                               | 14.33 / 22.65 / 16.16 | 14.05 / 23.85 / 19.90 |

†Note: the 100% overlapped segments still contain non-overlapped regions, overlap ratio of each segment ranges from 1% to 100%.

rest. The IPD features appended to the 7-channel STFT features were the same, which resulted in the feature dimension of each channel expanded from 257 to (1 + 6) * 257.

Given the back-end with parameters frozen that was trained in Stage-1, the front-end module of the joint model was trained using the Adam optimizer with a learning rate schedule similar to that described in [42]. The learning rate was linearly increased from 0 to 0.0001 by using the initial 1k iterations, kept until the 120k-th iteration, then exponentially decaying to 0.00001 at 240k iterations. In this work, we report the results of validation best models found after 200k of training iterations. The minibatch was 3000 frames, and 8 V100 GPUs were used for all the trainings.

4.5. Simulated vs. real multi-channel training data

Table 3 shows the WERs of the E2E MCASR models that were trained on simulated data or real data. We can make the following observations.

- When the model was trained on the multi-channel STFT features derived from the simulated training data, the overall WERs for Eval 1 and Eval 2 got improved from 21.42% to 19.86% and from 24.42% to 23.12%, respectively. The improvement was observed but limited due to the mismatch between training and testing.
- When the real data were used for the training, the WERs were substantially improved to 16.67% and 20.70% for Eval 1 and Eval 2, respectively. This implies that a substantial difference existed between the real and simulated training. It also suggests that the E2E MCASR could be sensitive to the mismatch of the training/testing conditions, and it is important to utilize the real training data even when the data quantity is limited.
d-vector for each speaker did not show any superiority, which means more accurate DOA estimation. Meanwhile, using a session-based model with the location bias achieved additional gains thanks to overlapped segments. When session-based decoding was applied, Eval 1 and Eval 2. Greater WER reduction was observed for the d-vector to the model could improve the ASR performance for both unbiased features, shallowly concatenating the angle feature or (Angle) (d-vector) Bias Info. Non-overlap / Overlap / Overall Non-overlap / Overlap / Overall

| Training Data | Location bias (Angle) | Speaker bias (d-vector) | Session-based Bias Info. | Eval 1 | Eval 2 |
|---------------|-----------------------|-------------------------|--------------------------|--------|--------|
| Real          | -                     | -                       | -                        | 14.41 / 24.95 / 16.72 | 14.04 / 24.58 / 20.31 |
| Real          | shallow               | -                       | -                        | 14.20 / 24.11 / 16.37 | 14.04 / 23.91 / 19.93 |
| Real          | shallow               | -                       | ✓                        | 14.23 / 23.61 / 16.28 | 14.01 / 23.23 / 19.51 |
| Real          | -                     | shallow                 | ✓                        | 14.38 / 24.03 / 16.49 | 13.96 / 24.15 / 20.04 |
| Real & Real+  | -                     | -                       | -                        | 14.33 / 22.65 / 16.16 | 14.05 / 23.85 / 19.90 |
| Real & Real+  | shallow               | -                       | -                        | 14.01 / 22.11 / 15.79 | 14.24 / 23.61 / 19.83 |
| Real & Real+  | shallow               | -                       | ✓                        | 14.06 / 20.85 / 15.57 | 14.22 / 21.29 / 18.44 |
| Real & Real+  | deep                  | -                       | ✓                        | 13.80 / 20.69 / 15.31 | 14.06 / 20.92 / 18.15 |

| Real & Real+  | deep                  | shallow†                | ✓                        | 14.13 / 19.88 / 15.38 | 14.09 / 20.61 / 17.98 |

† We didn’t apply deep concatenation for speaker bias because we observed degradation in our preliminary experiments.

4.6. Investigation of overlap proportion in training

To further improve the model capability to handle overlapped segments, we introduced the overlapped data Real+ for model training, where the overlapped data generation was described in Section 4.2.1. Table 4 shows how the use of the overlapped data during training affects the ASR performance, especially for the overlapped segments.

The baseline was the model trained on the original 60-hour multi-channel data. When we increased the ratio of overlapped segments to 30% in the 60-hour training data, we observed that the WERs of overlapped segments got improved for both Eval 1 and Eval 2. With further increasing the ratio to 60% or 100%, the gain was marginal for Eval 2, but it was substantial for the overlapped segments of Eval 1. It could be because the non-overlap to overlap distribution of Eval 1 was more similar to that of the validation set. Finally, when we simply joined Real and Real+ to form a 120-hour training set, we obtained overall WERs of 16.16% for Eval 1 and 19.90% for Eval 2. These results were close to 60-hour training with the data having 100% overlapped segments. It suggests that simply duplicating the real data with the same content would not benefit the E2E MCASR front-end training. Due to that the performances of 120-hour training and 60-hour fully (100%) overlapped training were on par, we just used the 120-hour set to train the model with biased information in the following experiments, representing that we have included overlapped segments in training.

4.7. Evaluation with bias information

Table 4 shows the WERs of the E2E MCASR models with different training sets and different kinds of bias information. Compared to the model that was trained on the 60-hour non-overlap data (Real) using unbiased features, shallowly concatenating the angle feature or d-vector to the model could improve the ASR performance for both Eval 1 and Eval 2. Greater WER reduction was observed for the overlapped segments. When session-based decoding was applied, the model with the location bias achieved additional gains thanks to more accurate DOA estimation. Meanwhile, using a session-based d-vector for each speaker did not show any superiority, which means the d-vector is not sensitive to partially overlapped segments. Overall, it suggests that both location and speaker biases are helpful for the E2E MCASR, especially for overlapped segments. The gain from the location bias is larger than that from the speaker bias as all directions can be covered in training.

Given the fact that the location bias yielded greater WER reduction, we continued investigation by using the angle-feature-based joint model trained on Real & Real+ as the basis. The overall WERs obtained by using the location bias for Eval 1 and Eval 2 were 15.57% and 18.44%, respectively, and were improved from 16.16% and 19.90% obtained with the unbiased features. The deep concatenation of the angle feature yielded the WERs for both sets (15.31% and 18.15%). Using the shallow-concatenated d-vector on top of the deep concatenation of the angle feature yielded better WERs for overlapped segments, as can be seen in the last two rows of Table 4. The pre-masking process greatly improved the WERs for the overlapped segments, while it slightly degraded the WERs for the non-overlapped segments. Applying pre-masking benefited more for Eval 2 which had more overlapped segments. We finally obtained the WERs of 15.47% for Eval 1 and 17.69% for Eval 2 with the training and decoding strategies, suggested by Fig 1 and the last row of Table 4.

5. CONCLUSION

This work investigated application of E2E MCASR to offline meeting transcription under practical settings. We started from an AED-based baseline ASR model trained with 75k hours of single-channel data, then improved the ASR performance of both non-overlapped and overlapped segments. We presented a practical way for leveraging a relatively limited amount of multi-channel data for joint front-end/back-end training and examined the impact of using real multi-channel training data. In addition, the ASR performance for overlapped segments was further improved by introducing the bias information which helps the front-end module focus on target speakers. Our meeting transcription experiment results showed that the framework could largely benefit from the real data training and the use of the bias information. 10+ % relative WER reduction was observed by replacing the simulation data with the real one. Overall, we achieved 27% relative WER reduction on real meeting recordings compared with the strong single-channel model trained on the large quantity of data.
