Organic semiconductors constitute promising candidates toward large-scale electronic circuits that are entirely spintronics-driven. Toward this goal, tunneling magnetoresistance values above 300% at low temperature suggested the presence of highly spin-polarized device interfaces. However, such spinterfaces have not been observed directly, let alone at room temperature. Thanks to experiments and theory on the model spinterface between phthalocyanine molecules and a Co single crystal surface, we clearly evidence a highly efficient spinterface. Spin-polarised direct and inverse photoemission experiments reveal a high degree of spin polarisation at room temperature at this interface. We measured a magnetic moment on the molecule’s nitrogen p orbitals, which substantiates an ab-initio theoretical description of highly spin-polarised charge conduction across the interface due to differing spinterface formation mechanisms in each spin channel. We propose, through this example, a recipe to engineer simple organic-inorganic interfaces with remarkable spintronic properties that can endure well above room temperature.

Technological progress in the past decade has been nothing short of astounding as revealed by our maturing information society. An important milestone will be to design not only electrical components but entire circuits that pervasively utilize the electron spin as well as its charge. In this vein, research has focused on the interface between ferromagnets (FM), whose current is spin-polarised, and organic semiconductors (OS), which have been identified as a promising medium to transport spin-encoded information due to low spin-orbit induced spin decoherence in this class of semiconductors ¹. A proof-of-concept experiment involving electrons far from the Fermi level E_F was recently reported ².

When integrated into devices, such interfaces can yield large values of magnetoresistance at low temperature due to transport at/near E_F, whether in the diffusive regime ³, in the ballistic regime across individual molecules ⁴ or in the tunneling regime ⁵. As supported by a phenomenological model, this latter result could underscore how, due to molecular chemisorption onto a transition metal surface, the OS’s molecules at the interface may exhibit a molecular orbital (MO) at E_F that extends the electrode conduction onto the first molecular monolayer ⁶. Due to exchange-split bands, the unequal density of states (DOS) of the two spin populations at E_F in the FM is then believed to lead to a spin-selective broadening of this MO ⁷, i.e. to a spin-polarised interface ⁷ that is termed a spinterface ⁸. This original mechanism of spinterface formation leads to band-induced spinterface states (BISS). Some of us have observed substantial (>500%), low-temperature tunneling magnetoresistance (TMR) across a fully organic barrier using Co/phthalocyanine (Co/Pc) interfaces. However, experiments have thus far not revealed large values of room temperature (RT) spin polarization (P) at/close to the Fermi level of such FM/OS interfaces, whether through spectroscopy techniques ⁹,¹⁰ or on actual devices ¹¹. In this sense, a validation of the promise behind the spinterface concept ¹², --- namely more efficient interfaces for spintronic applications --- is still lacking. Indeed, the spinterface concept is a pre-requisite for ballistic ¹, tunneling ³ and diffusive ³ regimes of...
transport, while spin transport in the diffusive regime also requires spin conservation during transport across the OS bulk.

**Results**

In what follows, we demonstrate that solving this riddle requires the study of FM/OS interfaces whose structure and electronic properties are well characterised. Given the link between photoemission (PE) and magnetotransport spectroscopy techniques, we have performed spin-polarised direct and inverse PE experiments at RT on interfaces between fcc Co(001) and MnPc (see the molecular schematic in the inset to fig. 2e) or H₂Pc as potential spinterface candidates.

The PE experiments reveal the presence of Pc-induced states close to E_F. In order to extract the signal coming only from the molecular sites, we adopt a subtraction procedure that takes into account the attenuation of the signal arising from ever deeper atomic sites away from the sample surface (see SI). We present in Fig. 1a the spin-resolved difference spectra of direct and inverse PE spectroscopy of Co/MnPc at RT (2.6 ML MnPc for direct and 2 ML MnPc for inverse PE) that are obtained by this subtraction procedure. Both direct and inverse PE experiments reveal significant (nearly no) spin ↑ (↓) intensity at/near E_F, which indicates a high P of the Pc-induced states in the vicinity of E_F. We note that very similar difference spectra (in direct PE) are also obtained in the case of H₂Pc, which shows that the central Mn³⁺ ion in MnPc plays a minor role in the formation of the spinterface. Assuming that the spin asymmetry of spectra is directly related to P (see Ref. 11), we can safely state that the RT P at E_F of the first two layers of MnPc or H₂Pc adsorbed on Co(001) reaches ~80% ± 10%, i.e. is opposite in sign to that of bare Co.

We now confirm the interfacial nature of P by examining the impact of additional Pc coverage. Upon appropriately subtracting the spin-resolved spectra of 1 ML H₂Pc/Co from those of 2 ML H₂Pc/Co, the intensity of the interface states is strongly reduced (see Fig. 1b): the second Pc layer contributes only 20% to the total intensity of the interface states of Fig. 1(a), which could reflect deviations from perfect layer-by-layer growth. The third ML does not contribute at all to the interface states’ intensity. We have also excluded the artefact of an altered Co interface magnetism on our analysis and conclusions (see SI).

To determine whether these interface states originate dominantly from the Co substrate or the Pc-overlayer, we compared data for photon energies of 20 eV and 100 eV (see Fig. 1c). From 20 eV to 100 eV, the cross section of photoionisation for free atoms decreases by over one order of magnitude for 2p states (C and N) while that for 3d states (Co and Mn) does not vary much. We expect that such a large effect for free atoms shall trend similarly in solid-state systems. Consequently, if the interface states were mainly of Co 3d character, they should also be present at 100 eV photon energy. However, the spin-resolved direct PE difference spectra at 100 eV show no indication for any Pc-induced structure at low binding energies. We thus conclude that the interface states are mainly of C or N 2p character.

Why does the interface between fcc Co(001) and MnPc or H₂Pc exhibit such a high P of PE at E_F, and this at RT? We propose the following key extension to the spinterface concept: highly efficient, thermally robust spinterfaces may be engineered by choosing the ferromagnet/molecule pair such that the dominant interfacial hybridization mechanism involves states at/near E_F from the ferromagnet (FM) and molecule that are present only in one spin channel. In addition to the well-known spinterface formation mechanism of spin-dependent broadening in that spin channel, this promotes the hybridization in the other spin channel between the FM’s surface states at the vicinity of E_F and MOs of the molecule. This mechanism ensures that energetically narrow and strongly spin-polarized hybrid interface states are pinned close to the Fermi level so as to drive the interface’s spintronic response. The resilience of the ensuing spinterface properties against thermal disorder are enhanced not only by a large FM Curie temperature but also when direct exchange coupling that results from the hybridization mechanism magnetises at least some of the molecule’s atoms.

When considering all electronic orbitals, ab-initio calculations on Co/Pc interfaces with unrelaxed atomic positions predicted a P that can reach ~25%, rather than the ~80% now measured experimentally. To more realistically describe the interface, our formalism now relaxes atomic positions and includes van der Waals forces so as to quantitatively reproduce the crucially important molecule-substrate distance inferred from x-ray standing wave measurements.

---

**Figure 1** | Direct and inverse photoemission reveals a high interface spin polarisation P using commonplace Co and phthalocyanine molecules.

(a) Spin-resolved difference spectra of direct (closed symbols; hv = 20 eV) and inverse (open symbols) photoemission (PE) spectroscopy at room temperature of Co/MnPc(2.6)(2.0) ML for direct/inverse PE reveal a P ~ +80% at E_F. (b) The Pc thickness dependence of the direct PE signal (hv = 20 eV) reveals that Pc-induced intensity at low binding energies is essentially confined to the interface. (c) Spin-resolved difference spectra of direct PE spectroscopy at room temperature of Co(3 ML)/MnPc(2.6 ML) for hv = 100 eV show no sign of any Pc-induced interface state, indicating that the interface states are mainly of C or N 2p character.
leads to a final distance $\Delta z$ between Co and the adsorbed molecule of 2.1 Å.

To unravel the formation of the spinterface, we first consider the ‘molecule-Co’ system as calculated using the actual atomic positions of the final interface, but we artificially impose $\Delta z = 6.6$ Å. We can then examine the states of the two systems using a common Fermi level in the absence of interactions between them (see Fig. 2a). We extrapolated the spin referentials found for finite exchange coupling at lower $\Delta z$ to those in the present case, at $\Delta z = 6.6$ Å, of vanishing exchange interactions between the two subsystems. The Co d-spin $\uparrow$ band crosses $E_F$, while the d spin $\downarrow$ band ends at $E_{F_d} = -0.7$ eV. Above this energy level, the spin $\uparrow$ sub-band exhibits only small DOS spikes that correspond to surface states. We note in particular one surface state at $E_F$ with a strong perpendicular component (z-DOS, black) compared to its planar counterpart (pl-DOS, magenta). We emphasize that these surface states also exhibit a z-component of DOS (gray). Near $E_F$, the molecule exhibits a MO only in the spin $\downarrow$ channel. Adsorption-induced displacements of the molecule’s atoms overall promote a slight energy shift ($\sim 30$ meV) of the MOs.

Figure 2 | The formation and properties of the Co/MnPc spinterface reflect distinct mechanisms in each spin channel. As the distance between molecule and the Co surface is reduced from (a) 6.6 Å to (b) 3.5 Å and to (c) the final position of 2.1 Å, p-d hybridization with the Co spin $\uparrow$ band causes energetically sharp, spin $\downarrow$ MOs in the z-DOS to disperse (red area of panel d), leading to a monotonous spin-$\downarrow$ z-DOS (black) at/near $E_F$ (right-hand graph of panel c). In the spin $\uparrow$ channel at the vicinity of $E_F$, there are neither Co d band states nor MOs but simply Co surface states, while planar states remain mostly unaffected, perpendicularly-oriented states experience the onset of hybridization. In particular, this hybridization may occur. Although fcc Co(001) has, near $E_F$, no p states and a highly spin-polarized d band, the flat, spin-degenerate s-band that crosses $E_F$ is essentially responsible, through s-d hybridization\textsuperscript{14}, for the only moderate 45% spin polarization of conduction electrons. Yet, referring to Fig. 2c, the...
spinteface formation involves Co s-states (gray datasets) only very weakly. Thus, although fcc Co(001) is obviously not half-metallic\textsuperscript{25,16}, the Co/MnPc spinteface shall strongly transmit the highly spin-polarized d-component of the Co DOS and attenuate the s and p components.

How is the Co d-band DOS transmitted onto the molecule in each spin channel? Prior to adsorption and in the spin↑ channel, the Co d band z-DOS intersects E_F and the z-DOS of the free molecule also exhibits a MO at/near E_F. Hybridization is therefore governed by the well-known spinteface mechanism of spin-dependent broadening of MOs due to band hybridisation\textsuperscript{25,8}. The resulting BISS (band-induced spinteface states) are shaded in red in fig. 2d. These BISS exhibit a flat, continuous energy dependence across E_F.

However, the molecule does not exhibit any sizeable, preexisting spin↑ z-DOS at the vicinity of E_F to hybridise with, and the Co surface's d-band doesn’t cross E_F. Another spinteface formation mechanism must therefore account for the appearance of entirely new, hybrid states in the spin↑ channel within −2.7 eV < E < −1.9 eV, i.e. at the vicinity of E_F, (see right-hand panel of Fig. 2c and the segment of the spinteface z-DOS shaded in green in fig. 2d). We propose that preexisting Co surface states (see left-hand panel of Fig. 2a and b) pin initially distant MOs to E_F. The narrow energy width of these surface-induced spinteface states (SIISS) reflects that of both the preexisting Co surface states – because the surface atoms are missing bonds – and of the preexisting MOs. Due to the Pauli exclusion principle, these newly formed SIISS cannot occupy the spin↑ states since they are already occupied by Co, and hence appear only in the spin↑ channel. The presence of two sharp, tall peaks near E_F reflects a lifting of degeneracy induced by upward (downward) buckling of the benzene rings below(at) E_F along each of the two orthogonal axes that define the free molecule’s 4-fold symmetry. This underscores how crucial it is to fully relax the interface structure if one wishes to study SIISS.

Since surface states naturally lie at the vicinity of E_F, so shall SIISS. Although SIISS may appear as energetically sharp DOS peaks, which could reflect localization, SIISS contribute to conduction across the interface. Indeed, the spectral signature of the SIISS appears in the spin↑ z-DOS of both Co surface and molecular sites (compare graphs of fig. 2c or refer to the SI). Focusing now on the DOS that contributes to transport at RT, we present in Fig. 3c–d spintefarised spatial maps, taken along the dashed line of Fig. 3a, of the Co/MnPc interface DOS within E_F − 25 meV < E < E_F + 25 meV (see Fig. 3b). Aside from the central Mn site, the remaining N and C sites exhibit very large positive P at E_F thanks to electronic states that are clearly hybridised with the Co interface atoms. In fact, these interface states are present on all atomic species of the molecule (fig. 2e) and their amplitude trends with the number of molecular nearest-neighbours for a given Co spinteface site.

At E_F, both the energetically smooth BISS in the spin↑ channel and the energetically sharp SIISS in the spin↑ channel define the sign and amplitude of the spinteface’s P. Due to large part to the energetically sharp SIISS that crosses E_F, we find that P = 80%. Thus, considering the limitations of the comparison, we find that both theory and the direct/inverse PE experiments yield the same sign and high amplitude of P at E_F (see fig. 1a and 2e). Furthermore, peaks in the spin↑ channel (see Fig. 1a) and DOS spectra (see fig. 2d) at ~E = E_F = −0.3(−1.0) eV underscore a reasonably good agreement between theory and the direct PE experiment thanks to its good energy resolution (130 meV), while a qualitative agreement is found with inverse PE.

Since both PE experiments and ab-initio theory describe how the molecule’s sites are spin-polarised, we now consider the magnetic properties of the spinteface. Referring to the on-site local magnetisation density map of Fig. 4a, our theory indicates that a strong antiferromagnetic (AF) coupling between Co and the numerous C benzene sites leads to a total magnetic moment for all C atoms of ~0.22 μB. Within a Hund’s rule description, this is expected since the Co d orbitals are more than half-filled. Only the partially filled d↓ band may then hybridize, so that the coupling between C and Co is mediated essentially by minority electrons. Direct p-d coupling then leads to an exchange splitting of the C majority and minority DOS that is opposite in direction to that of Co.

The magnetic coupling of N sites is more subtle. Indeed, although N is coupled AF to Mn for free MnPc, molecular adsorption onto Co leads, through d-d hybridization, to ferromagnetic (F) coupling between Mn and Co (as expected since the Mn d band is less than

![Figure 3](https://www.nature.com/scientificreports/)

**Figure 3 | The Co/MnPc spinteface as a highly spin-polarised current source.** (a) Adsorption geometry of MnPc on Co(001). The spin↑ and↓ z-DOS within E_F − 25 meV < E < E_F + 25 meV: (b) SIISS (BISS) lead to a sharp (monotonous) energy dependence at E_F; and (c–d) spatial charge density maps, taken along the dashed line of panel (a), show how the numerous C and N sites of MnPc exhibit a highly spin-polarised density of states at E_F that, furthermore, are hybridised with Co states and thus contribute to conduction. The maps are in units of e Å\(^{-3}\).
Both contribute to the high P at EF, their magnetisations are in fact coupling onto all N and C pyrrole sites. Thus, although C and N sites both contribute to the high P at EF, their magnetisations are in fact opposite to one another.

If the molecule z-DOS is spin-polarized at EF owing to BISS and SISS, then the molecule’s π DOS at EF should be spin-polarised. To support this theoretical description of spininterface magnetism, and as a tenet of spintronically active interfaces, we have performed x-ray magnetic circular dichroism (XMCD) experiments at the N K edge of MnPc’s 8 nitrogen sites (see Methods). Referring to Fig. 4b, we witness XMCD intensity within the energy range corresponding to final 2p π (i.e. that probe the z-DOS just above EF), but not 2p σ, states. This unequivocal XMCD signal is very strong compared to the stray XMCD signal obtained when MnPc is adsorbed onto Cu(001) (see Fig. 4c), for which one does not expect the presence of on-site magnetic moments. The sharp absorption peak at 401 eV in the Cu/MnPc spectrum, which leads to the derivative-like XMCD signal, is in fact due to low-temperature N2 adsorption. Since these K edge transitions, we can only state that an orbital magnetic moment appears on the final N 2p π states at the Co/MnPc spininterface, the sign of which is in agreement with that found theoretically. This experimentally confirms that the N z-DOS is spin-polarized as we have described theoretically.

Discussion

We now discuss spintronics prospects for these Co/Pc spininterfaces. Indeed, an ideal spin-polarized current source (IspCS) should 1) exhibit a very high degree of spin polarisation P that 2) endures well above RT for technological applications; 3) be both cheap and straightforward to synthesize considering existing industrial capabilities; 4) be compatible with miniaturisation challenges at the nanoscale; and 5) provide an easy integration path with a semiconductor so as to enable transport of, and operations on, the highly spin-polarised current. Behind criterion 5 lies the original promise of the spintronics field to promote the rise of an electronics in which not only individual electronic components (e.g. read heads in hard disks) but entire electronic circuits are conceived so as to encode and transport information using the electron spin.

Candidates toward an IspCS include half-metallic ferromagnets, which ideally conduct electrons of only one spin direction and could, using merely a band hybridisation mechanism of spininterface formation, lead to efficient spininterfaces. Such materials have been studied using direct PE and been integrated into devices with sizeable P, not only at low temperature but also at RT. However, this track fails criteria 3 and 4 for an IspCS because such materials are sensitive to disorder. Dilute magnetic semiconductors offer an interesting solution to criterion 5, but lose their half-metallic property well below RT. Another track is to resistively filter the current so as to spin-polarise it. Fe/MgO-based IspCS accomplish this through tunneling across MgO and can reach P = 85% but this resistive solution to spin-filtering a) must involve several dielectric monolayers that b) must be of finite lateral extent in order to promote kπ conservation. This resistive solution is therefore not as practical toward nanoscale applications (criterion 4) as a conductive one involving merely an interface that can scale down laterally to the individual molecule.

In contrast, the Co/Pc interface involves differing spininterface formation mechanism in each spin channel to yield a high P (criterion 1). Since both mechanisms are driven by direct rather than indirect hybridisation, the resulting current source is spin-filtered across a conductive interface (criterion 4) and inherits the large temperature resiliency of the Co interface magnetisation...
(criterion 2). Such spinterfaces utilize cheap, abundant materials that can be straightforwardly deposited and will not degrade when processed appropriately into devices even at typically large process temperatures (criterion 3). Finally, with its spin-polarized molecular plane, this IpSpCS candidate elegantly mitigates the conductivity mismatch problem associated with interfaces between metals and semiconductors, which is promising toward satisfying criterion 5, at the very least when considering a Pc OS. Indeed, the hybridization of wavefunctions from the interfacial molecular plane of high P with those of subsequent molecular layers away from the interface is intrinsically favored. Furthermore, referring to Fig. 3, conductivity is substantially lowered when going from Co to the Pc spinterface due to a strongly attenuated spin $j$ channel. These attributes of the Co/Pc spinterface represent important pre-requisites toward a future room-temperature demonstration of sizeable spin transport in the diffusive regime.

In conclusion, using direct and inverse PE, we have explicitly measured the interface contribution to the spin polarized DOS for Pc monolayers on Co(001), the so-called spinterface. At room temperature, the spinterface around the Fermi level is strongly dominated by the majority channel, leading to a spin polarization $\sim 80\%$. Thus, our work on Co/Pc interfaces provides a direct proof of the promise behind the spinterface concept, which was initially described in terms of band-induced spinterface states (BISS) \cite{6}. We propose to extend this concept to include the additional spinterface formation mechanism of surface-induced spinterface states (SISS). SISS appear if the FM band of the dominant hybridisation mechanism is absent near $E_F$ in one spin channel. This criterion is for example satisfied in the spin $\uparrow$ channel by strong ferromagnets such as Co or Ni. By combining BISS and S ISS in separate spin channels, the spintronic response of these spinterfaces is not only large but can potentially be controlled through external stimuli. For example, due to the adsorbed molecule’s lower symmetry, we find that rotating the magnetisation by $90^\circ$ shifts the SISS peak at $E_F$ by $\sim 1$ meV, leading to a $10\%$ change in $P$. Underscoring this effect is the spinterface’s magnetic anisotropy, which can itself in principle be controlled using an electric field (e.g. Ref. 29) so as to more substantially alter the spinterface properties.

Finally, these spinterfaces constitute a strong candidate toward satisfying the five criteria for an IpSpCS, so as to pervasively use the electron spin, not simply in individual electronic components, but in future electronics industrial designs. Indeed, the $P$ amplitude that we extract from spectroscopy experiments at RT and from theory is in agreement with that inferred from low-temperature TMR experiments across Co/Pc/Co nanojunctions. Thus, our results lay out a materials strategy for TMR devices with sizeable TMR at RT, as a stepping stone toward subsequent spin transport in the diffusive regime at RT. Beyond future Co/Pc-based spintronic demonstrators based on the well-established tunneling mechanism of spin-polarized transport, we are presently working to extend these spinterface-inductcued IpSpCS concepts to memristive organic interfaces\textsuperscript{30,31} so as to pave the way for robust organic multifunctional devices alongside their inorganic counterparts\textsuperscript{32}.

**Methods**

To prepare samples for x-ray absorption (XAS), spin-polarised photoemission (SPARPES) and spin-polarised inverse photoemission (SPIPEX) experiments, we used a Cu(100) single crystal as substrate. It was cleaned by sputtering and annealing at 900 K. MnPc and H$_2$Pc were sublimated ($P \sim 10^{-6}$ mbar, 1 monolayer (ML) = 0.38 nm) so as to form ultrathin films on Cu(100) or on Co(100) layers epitaxially grown on Co(001). XAS were acquired (beamlines SIM at SLS and ID8 at ESRF) in total electron yield mode ($P < 2 \times 10^{-9}$ mbar) by reversing both the circular polarization of the photons and the sign of the external magnetic field. XAS were measured at the $N$ K edge. The XMCD signal (ID8) was normalised to the height of the absorption edge step. The incidence angle was $\sim 45^\circ$ to be sensitive to both in- and out-of-plane orbitals. We affirm a successful subtraction of the Co $L_2$ harmonics from the N K edge XMCD. Indeed, the N K edge XMCD is of same sign as the remnant Co $L_2$ harmonic. Since the Co $L_3$ and $L_2$ harmonics are necessarily of opposite sign, the measured XMCD cannot arise from the Co $L_3$ harmonic. Note that beamline ID8 exhibits a strong C absorption within the background spectrum that precluded XAS/XMCD experiments at the C K edge.

SPARPES experiments were undertaken on the Cassiopea Beamline at Synchrotron Soleil using photons at 20 and 100 eV and with the horizontal electric field impinging upon the sample at $45^\circ$. Photoelectrons were then collected along a direction normal to the sample surface. The energy resolution is 130 meV.

SPIPEX experiments were performed using a collimated and transversely polarised electron beam with 25% polarization from a GaAs photocathode. We used the projectore augmented wave (PAW) pseudopotentials as provided by VASP\textsuperscript{33}. The van der Waals (vdW) weak interactions were computed within the so-called GGA-D2 approach developed by Grimme\textsuperscript{34} and later implemented in the VASP package\textsuperscript{35}. Our formalism can correctly reproduce the experimentally determined atomic distances between molecular sites and metallic sites. Fcc Co(001) and fcc Cu(001) surfaces were modeled by using a supercell of 3 atomic monolayers of $8 \times 8$ atoms separated by a vacuum region. The lattice vector perpendicular to the surface is $\sim 3$ nm. This results in a supercell of 289 atoms, including the 57 atoms of the MnPc molecule. Since experiments used cobalt epitaxially grown on Cu, we used the fcc lattice parameter of 0.36 nm for both cobalt and copper. We have found that additional monolayers will not change significantly the results\textsuperscript{36}. A kinetiic energy cutoff of 450 eV has been used for the plane-wave basis set for our study of a single molecule on metallic surfaces, we used the first Brillouin zone of DOS were calculated using a 1 meV energy mesh and a Gaussian broadening of 20 meV full-width at half-maximum. Spin-orbit coupling was included perturbatively in the augmentation region at each atomic site.

We thank the ESRF and SIM beamline staff for technical assistance. F. Djehghoul thanks «Le Ministère de l’enseignement Supérieur et de la Recherche Scientifique d’Algérie» (MESRS) for financial support. We acknowledge financial support from ANR-PNANO grants ANR-06-NANO-053-01 and ANR-06-NANO-053-02, the EC Sixth Framework Program (NMP3-CT-2006-033370), the CNRS-PICS Program No. 5275, the Deutsche Forschungsgemeinschaft (DFG), the Center for Functional nanostructures (CFN), the International Center for Frontier Research in Chemistry and the French German University. S. Javaid thanks the Pakistani government (HEC) for financial support. This work was performed using HPC resources from GENCI-CINES Grant 2012-gem1100.

Author contributions

J.A. purified the molecules. W.W., R.B. and M.B. conceived the photoemission experiments. F.D., M.C., L.J., M.B., S.B., E.B., W.W. and P.S. M.B. prepared final figures, assisted by W.W., M.C., F.I., P.O. M.B., S.B., E.B. and W.W. F.I., S.J. and A.J. carried out the calculations. F.I., M.B., M.A., P.O., F.S., M.B. and N.B. analysed the data. M.A. conceived the ab-initio theory along with S.B., P.O., P.T., F.S., M.B., R.M., T.M., S.J., J.-P. K. and E.B. carried out the experiments. S.B., P.O., F.S., M.B. and N.B. analysed the data. M.A. conceived the ab-initio theory along with M.B., S.B., E.B. and W.W. F.I., S.J. and A.J. carried out the calculations. F.I., M.B., M.A., S.B., W.W. and E.B. analysed the data. M.B. wrote the paper, assisted by W.W., M.A., S.B., E.B., W.W. and P.S. M.B. prepared final figures, assisted by W.W., M.C., F.I., P.O. and S.B. All authors discussed the results and commented on the manuscript.
