(Dated: November 12, 2020)

Quantum conversion or interface is one of the most prominent protocols in quantum information processing and quantum state engineering. We propose a photon-phonon conversion protocol in a hybrid magnomechanical system comprising a microwave optical mode, a driven magnon mode and a mechanical-vibrating mode. The microwave photons in the optical cavity are coupled to the magnons by the magnetic-dipole interaction, and the latter are coupled to the mechanical phonons by the magnetostrictive interaction. With strong photon-magnon interaction and strong driving on magnon, an effective Hamiltonian is constructed to describe the conversion between photons and phonons nearby their resonant point. The cavity-magnon system can then play the role of a quantum memory. Moreover, the faithfulness of the photon-phonon conversion is estimated in terms of fidelities for state evolution and state-independent transfer. The former is discussed in the Lindblad master equation taking account the leakages of photon, phonon and magnon into consideration. The latter is derived by the Heisenberg-Langevin equation considering the non-Markovian noise from the structured environments for both optical and mechanical modes. The state-evolution fidelity is found to be robust to the weak leakage. The transfer fidelity can be maintained by the Ohmic and sub-Ohmic environments of the photons and is insensitive to the $1/f$ noise of the phonons. Our work thus provides an interesting application for the magnon system as a photon-phonon converter in the microwave regime.

I. INTRODUCTION

The cavity-magnon system is a rapid-developing mesoscopic platform for quantum information processing. As an active topic of research, it has been theoretically investigated [1, 2] and experimentally demonstrated [3–6] in the perspective of cavity quantum electrodynamics (cQED) during the past decade. Following the circuit-QED [7] systems and the semiconductor microcavities systems (such as quantum dots embedded in cavities [8, 9]), the cavity-magnon system actually becomes an alternative candidate to exploit the ubiquitous effects of cQED in the strong-coupling regime.

Typically in a cavity-magnon system, a magnet-spin ensemble in a single-crystal yttrium iron garnet (YIG) sphere is loaded into a high-Q cavity. Down to the quantum level, it is found that the Kittel mode of the spin ensemble (the ground state) in the YIG sphere could be strongly coupled to the microwave photons in a cavity-mode, and in the mean time the magnons are coupled to the phonons describing the mechanical vibration of the same sphere (See the diagram in Fig. 1). Then a cavity-magnon system could be considered as a cavity-magnomechanical system taking inspiration from the cavity optomechanics, where the optical mode is directly coupled to the mechanical vibration of the movable mirror via radiation pressure [10]. Significant progresses regarding the mechanical vibration have been reported to demonstrate the quantum advantages, such as the phonon cooling in a non-Markovian environment [11], the quantum entanglement between mechanical elements and cavity modes [12, 13], and the quantum state transfer between photon and phonon [14]. In light of displaying the quantum characteristics, it is interesting to develop original ideas in the existing hybrid quantum systems [10, 15–18] to the cavity-magnomechanical system. For example, the first implementation of the photon-magnon-phonon interaction was addressed in Ref. [19], based on which the photon-magnon-phonon entanglement in cavity magnomechanics has been proposed in Ref. [20].

In terms of quantum conversion, protocols for light-matter interface and state-transfer have been implemented with atomic systems under cavity-QED [21, 22]. The scheme about quantum state conversion between microwave and optical photons was proposed via an optoelectromechanical interface [23]. Optomechanical systems can also serve as a light-matter interface, in which quantum information and quantum fluctuations originally encoded in an optical field can be reversibly mapped to a mechanical oscillator with a much smaller decay rate [24, 25], by which the mechanical oscillator serves as a quantum network node [19, 20] for potential information storage and processing [26]. In this work, we present a protocol for photon-phonon conversion in the cavity magnomechanical system [20] on account of the fundamental interest in the physical process, also exploiting the strong coupling for the magnon-phonon and the magnon-phonon interactions and the negligible decay rate of the phonon. Note the phonon in YIG sphere decays with a rate about 100Hz [19], much smaller than its own frequency and that of the photons.

The strong coupling inside a hybrid system opens a

* Email address: jingjun@zju.edu.cn
door to study the physics of virtual processes governed by the interaction Hamiltonian and leads to many interesting phenomena and applications in quantum engineering [27–29]. For example, the interesting Bell states, GHZ states [30] and NOON states [31] can be generated in the strongly coupled circuit-QED systems by virtue of the multiple-photon process. In a similar way one can have an effective Hamiltonian describing the indirect coupling between photon and phonon at their resonant point via the virtual process of magnons. In particular, the effective coupling obtained by the second-order perturbation theory [31, 32] supports a novel conversion protocol between the mechanical-oscillation and the microwave optical mode, resembling the conventional one in the optomechanical systems.

The rest part of this work is structured as following. In Sec. II, we introduce the hybrid quantum model and derive the effective Hamiltonian for the photon-phonon conversion mediated by the magnon mode. In Sec. III, the effective Hamiltonian is confirmed by comparing to the original Hamiltonian with respect to the effective coupling strength and is phenomenologically tested in terms of the state evolution under the leakage of photon, magnon and phonon by a Lindblad master equation. While in Sec. IV, a state-independent transfer fidelity determined by the effective Hamiltonian is derived through a microscopic analysis via the Heisenberg-Langevin equation. It is shown that our conversion protocol can be implemented with a high fidelity under certain structured environments for the photon mode. In Sec. V, we discuss the Kerr effect about the magnon mode on the effective Hamiltonian and then summarize the whole work.

II. MODEL AND THE EFFECTIVE HAMILTONIAN

![FIG. 1. (Color online) Model diagram: a YIG sphere is placed inside a microwave cavity near the maximum magnetic field of the cavity mode, and simultaneously in a uniform bias magnetic field, which establishes the magnon-photon coupling. The magnon mode is driven by a microwave source (with a magnitude \(\Omega_d\)) to enhance the magnomechanical coupling.](image)

We consider a hybrid cavity magnomechanical system as shown in Fig. 1, which is constituted by cavity-mode photons, magnons, and phonons [20] down to the quantum level. The magnons are embodied by a collective motion of a large number of spins in a ferrimagnet, e.g., a YIG sphere. The magnon mode is coupled to the cavity photons via the magnetic dipole interaction. The coupling between magnons and phonons is mediated by the magnetostrictive interaction. In particular, the temporal-varying magnetization induced by the magnon excitation inside the YIG sphere leads to the deformation of its geometrical structure, which forms the vibrational modes (phonons) of the sphere. The sphere size is considered to be much smaller than the wavelength of the microwave photons, such that the magnetic dipole interactions are isotropic and the effect of radiation pressure (proportional to the photon number \((a^\dagger a)\) over the sphere is negligible. The system Hamiltonian thus reads (\(\hbar = 1\))

\[
H_S = \omega_a a^\dagger a + \omega_m m^\dagger m + \omega_b b^\dagger b + i\Omega_d (m^\dagger e^{-i\omega_d t} - me^{i\omega_d t}) + g_{ma} (am^\dagger + a^\dagger m) + g_{mb} m^\dagger m (b + b^\dagger). \tag{1}
\]

Here \(a(a^\dagger), m(m^\dagger)\) and \(b(b^\dagger)\) are the annihilation (creation) operators of the photon, magnon and phonon modes, respectively. \(\omega_a, \omega_m\) and \(\omega_b\) are their respective eigen-frequencies. The Rabi frequency \(\Omega_d = \sqrt{5/4\gamma}\sqrt{N}B_0\) describes the coupling strength between the driving field with amplitude \(B_0\) and frequency \(\omega_d\) and the magnon mode, where \(\gamma\) is the gyromagnetic ratio and \(N\) is the number of spins [20]. The magnet-spin ensemble has good coherence properties [33] and strong dipole transitions for efficient coupling to the microwave photons. Thus the magnon-microwave coupling strength \(g_{ma}\) can be larger than the dissipation rates of both cavity and magnon modes, \(\kappa_a, \kappa_m\), entering into the strong-coupling regime, \(g_{ma} > \kappa_a, \kappa_m\). In the Hamiltonian of Eq. (1), we have employed the rotating-wave approximation, i.e., \(g_{ma} (a + a^\dagger)(m + m^\dagger) \rightarrow g_{ma} (am^\dagger + a^\dagger m)\), that is valid when \(\omega_a, \omega_m \gg g_{ma}\) [19]. The single-magnon magnomechanical coupling strength \(g_{ma}\) is typically small considering the large frequency mismatch between the magnon and the phonon modes, yet it can be compensated by a strong parametric drive \(\Omega_d\). In this case, the magnomechanical coupling is described by a radiation pressure-like, dispersive interaction Hamiltonian \(g_{mb} m^\dagger m (b + b^\dagger)\).

It is convenient to change the description of the microwave photon mode and the magnon mode by switching to a frame rotating at the driving frequency \(\omega_d\). Applying the unitary transformation \(U = \exp(\omega_d t a^\dagger a + \omega_d t m^\dagger m)\) makes the driving terms time independent [10], and generates a rotating Hamiltonian \(H'_S = U H S U^\dagger - iU \partial U^\dagger / \partial t\) of the form

\[
H'_S = \Delta_a a^\dagger a + \Delta_m m^\dagger m + \omega_b b^\dagger b + g_{mb} m^\dagger m (b + b^\dagger) + g_{ma} (am^\dagger + a^\dagger m) + i\Omega_d (m^\dagger - m). \tag{2}
\]

where \(\Delta_a = \omega_a - \omega_d\) and \(\Delta_m = \omega_m - \omega_d\). The magnon mode under driving is assumed to have a large expec-
tation value \(|\langle m | \rangle \equiv M \gg 1\), which allows to linearize \([10, 34]\) the system dynamics by writing the operator \(m = M + \delta m\) with \(\delta m\) describing the fluctuation of the magnon mode. The Hamiltonian \(H'_S\) turns out to be

\[
H = H_0 + V,
\]

\[
H_0 = \Delta_\alpha a^\dagger a + \Delta_m \delta m^\dagger \delta m + \omega_b b^\dagger b, \tag{3}
\]

\[
V = G(\delta m^\dagger + \delta m)(b + b^\dagger) + g(\delta m^\dagger a + a^\dagger \delta m),
\]

where \(g = g_{ma}\), and \(G = M g_{mb}\) is the effective magnon-mechanical coupling strength. During the derivation over Eq. (3), all the linear terms have been omitted by an appropriate modulation over the detunings, since they indicate the presence of the average displacements. Then we only keep the quadratic interaction \(V\) \([10]\). For simplicity, we apply the convention \(\delta m \rightarrow m\) in the following content.

To realize the photon-phonon conversion assisted by the magnon mode via the linearized approximation of the Hamiltonian in Eq. (3), generally one can extract an effective transition from the near-degenerate subspaces based on the standard perturbation theory with respect to the coupling strengths \(g\) and \(G\). When the photon-frequency \(\omega_b\) is near-resonant with the detuning frequency \(\Delta_a\), and both \(\omega_b\) and \(\Delta_a\) are far-off-resonant from the detuning frequency \(\Delta_m\), i.e., \(\omega_b \approx \Delta_a \gg g, G\) and \(|\omega_b - \Delta_m| \gg g, G\), it is found that the tensor-product state \(|n_a l_m k_b\rangle = |n_a l_m \rangle |k_b\rangle\) is near-degenerate with \(|(n - 1) a l_m (k + 1) b\rangle\). Here the subscripts \(a, m, b\) respectively represent the photon, magnon and phonon modes, and \(n, l, k\) indicate their individual Fock-states.

FIG. 2. (Color online) All the second-order (leading-order) paths involving arbitrary base-pair \(|nlk\rangle \equiv |n_a l_m k_b\rangle\) and \(|(n - 1) l(k + 1)\rangle\). Blue solid lines mark the transitions mediated by the photon-magnon coupling. Red long-dashed lines mark the transitions mediated by the magnon-phonon coupling.

The indirect connection for any two eigenstates \(|i\rangle\) and \(|j\rangle\) of the unperturbed Hamiltonian \(H_0\) can be constructed to the leading order by \([30, 32]\)

\[
ge_{\text{eff}} = \sum_{n \neq i, j} \frac{V_{n i} V_{n j}}{\omega_i - \omega_n}, \tag{4}
\]

where \(V_{n m} \equiv \langle n | V | m \rangle\) and \(\omega_n\) is the eigenenergy of state \(|n\rangle\), provided the interaction Hamiltonian \(V\) is regarded as a perturbation to \(H_0\).

A good approximation of the effective Hamiltonian describing the transition between arbitrary base-pair \(|nlk\rangle\) and \(|(n - 1) l(k + 1)\rangle\) can be analytically obtained using the preceding second-order perturbation theory. It can be expressed in the form

\[
H_{\text{eff}} = (\Delta_a + \epsilon_1)|nlk\rangle\langle nlk| + (\epsilon_2)|\omega_b + \delta\rangle\langle\omega_b + \delta| + \text{c.c.}, \tag{5}
\]

where \(\epsilon_1\) and \(\epsilon_2\) are the energy shifts due to the effective coupling for the states \(|nlk\rangle\) and \(|(n - 1) l(k + 1)\rangle\), respectively, and \(g_{\text{eff}}\) is the effective coupling strength. These are three coefficients to be determined in this ansatz.

We first consider the energy shift \(\epsilon_1\) for the state \(|nlk\rangle\). Summarizing all the 6 paths from \(|nlk\rangle\) and back to itself through an intermediate state (see Fig. 2), e.g., \(|nlk\rangle \rightarrow |(n - 1) l(k + 1)\rangle \rightarrow |nlk\rangle\), one can obtain the second-order energy correction (shift) \(\epsilon_1\) according to Eq. (4)

\[
\epsilon_1 = \frac{\langle n - l \rangle g^2 - \langle k - l \rangle G^2}{\Delta_a - \Delta_m + \omega_b - \Delta_m - (l + k + 1) G^2} = \frac{(n - l) g^2 - (k - l) G^2}{\Delta_a - \Delta_m + \omega_b - \Delta_m - (l + k + 1) G^2}. \tag{6}
\]

Similarly the energy shift \(\epsilon_2\) for the state \(|(n - 1) l(k + 1)\rangle\) is found to be

\[
\epsilon_2 = \frac{\langle n - l - 1 \rangle g^2 - \langle k - l + 1 \rangle G^2}{\Delta_a - \Delta_m + \omega_b - \Delta_m - (m + l + 2) G^2} = \frac{(n - l - 1) g^2 - (k - l + 1) G^2}{\Delta_a - \Delta_m + \omega_b - \Delta_m - (m + l + 2) G^2}. \tag{7}
\]

Note an exact photon-phonon resonance facilitated by Eq. (5) allows a complete Rabi oscillation between arbitrary \(|nlk\rangle\) and \(|(n - 1) l(k + 1)\rangle\), which requires that the first two terms in Eq. (5) constitute the identity operator in the relevant subspace. Thus \(\Delta_a + \epsilon_1 = \omega_b + \epsilon_2\). Assuming the distance between \(\Delta_a\) and \(\omega_b\) is \(\delta\), one can then have

\[
\delta = \Delta_a - \omega_b = \epsilon_2 - \epsilon_1 = \frac{G^2}{\omega_b - \Delta_m} - \frac{g^2}{\Delta_a - \Delta_m - \omega_b + \Delta_m} \tag{8}
\]

\[
= \frac{G^2}{\omega_b - \Delta_m} - \frac{g^2}{\Delta_a - \Delta_m} - \frac{G^2}{\omega_b + \Delta_m} = \frac{g^2}{\omega_b - \Delta_m} + O(\delta^2) = A - B \delta + O(\delta^2),
\]

where \(A \equiv \frac{(G^2 - g^2)}{\omega_b - \Delta_m} - \frac{G^2}{\omega_b + \Delta_m}\), \(B = \frac{g^2}{\omega_b - \Delta_m}\), and \(O(\delta^2)\) represents all the higher orders of \(\delta\) from the first order in Taylor expansion. Then \(\delta\) is consistently solved as \(\delta = A/(1 + B)\) up to the second-order correction. Note \(B \approx O(g^2/\omega_b - \Delta_m^2)\), so that up to the second order of the coupling strengths \(g\) or \(G\), we have

\[
\delta = \frac{G^2 - g^2}{\omega_b - \Delta_m} - \frac{G^2}{\omega_b + \Delta_m}. \tag{9}
\]

Note \(\delta\) is a Fock-state-independent coefficient in comparison to both \(\epsilon_1\) and \(\epsilon_2\).
Next we consider the contribution from the two paths connecting \( |nlk\rangle \) and \( |(n-1)(l+1)k\rangle \) in Fig. 2, i.e., \( |nlk\rangle \rightarrow |(n-1)(l+1)k\rangle \rightarrow |nlk\rangle \rightarrow |(n-1)(l+1)k\rangle \) and \( |nlk\rangle \rightarrow |n(l-1)(k+1)\rangle \rightarrow |nlk\rangle \rightarrow |n(l-1)(k+1)\rangle \), to their effective coupling strength. By virtue of Eq. (4), one can have

\[
g_{\text{eff}} = \left( l+1 \right) \frac{\sqrt{n(k+1)}Gg}{\Delta - \Delta_m} - \frac{l \sqrt{n(k+1)}Gg}{\omega_b - \Delta_m} = \left( l+1 \right) \frac{\sqrt{n(k+1)}Gg}{\omega_b} + \frac{Gg}{\omega_b - \Delta_m} G_g \tag{10}\]

up to the second order of the coupling strengths \( g \) or \( G \). Eventually the effective Hamiltonian in Eq. (5) can be written as

\[
H_{\text{eff}}^{(nk)} = g_{\text{eff}} \langle |nlk\rangle \langle (n-1)(l+1)k| + h.c. \rangle = g_{\text{eff}} \langle |nlk\rangle \langle (n-1)(k+1) \rangle + h.c. \rangle \otimes |l\rangle \langle l| \tag{11}\]

The effective Hamiltonian extended to the whole Hilbert space of photon and phonon is therefore found to be

\[
H_{\text{eff}} = \hat{G}(ab^\dagger + ba^\dagger). \tag{12}\]

Here

\[
\hat{G} = \frac{Gg}{\omega_b - \Delta_m} \tag{13}\]

is the effective coupling strength for the two modes, which is in the same order as the deviation \( \delta \) of the avoided level-crossing point from \( \omega_b \). More importantly, both \( \hat{G} \) and \( \delta \) are Fock-state independent that is the key to a generic conversion rather than the state transfer in special subspaces. It should be emphasised that the similar effective Hamiltonian could also be obtained by adiabatic elimination [35–37] in analog hybrid systems.

The effective Hamiltonian in Eq. (12) is conserved in the excitation number, so that it can be written in a block-diagonal matrix formation on the Fock-state basis. For example, if we focus on the single-exciton subspace \( \{|001\} \equiv |0\rangle_a |0\rangle_m |1\rangle_b, |100\rangle \} \) in which the magnon remains at the ground state, then we can have an X-gate:

\[
H_{\text{eff}}^{(1)} = \begin{bmatrix} 0 & \hat{G} \\ \hat{G} & 0 \end{bmatrix} = \hat{G} \sigma_x. \tag{14}\]

We plot the associated energy levels in Fig. 3, where the eigenvalues \( \{E_0\} \) and the eigenstates of the Hamiltonian in Eq. (3) are obtained by the standard numerical diagonalization method in a truncated Hilbert space. An avoided level-crossing (distinguished in the dark circle) presents between two eigenstates of the original Hamiltonian in Eq. (3), when the detuning frequency of photon \( \Delta_a \) approaches (but not exactly equals) the frequency of phonon \( \omega_b \). The mutual interaction between the photon and the magnon and that between the magnon and the phonon induce a negative shift from \( \Delta_a = \omega_b \). Here we choose \( \Delta_m = 1.7 \omega_b \) to avoid unnecessary exciting of the magnon mode. When the system is prepared as \( |100\rangle \), it can be converted to \( |001\rangle \) via a half Rabi oscillation determined by \( H_{\text{eff}}^{(1)} \) after a duration \( \pi/|2\hat{G}| \).

\[\text{FIG. 3. (Color online) Normalized energy-level diagram and avoided level-crossing for the photon-phonon conversion in a single-exciton subspace, which are plotted as a function of the detuning frequency } \Delta_a/\omega_b. \text{ Apparently the interactions in the system shift the avoided-level-crossing point from } \Delta_a/\omega_b = 1 \text{ by } \delta \text{ as given by Eq. (9). Here we fix } \Delta_m = 1.7 \omega_b \text{ and } g = G = 0.1 \omega_b.\]

\[\text{FIG. 4. (Color online) Normalized energy-level diagram and avoided level-crossing in a double-exciton subspace, which are plotted as a function of the detuning frequency } \Delta_a/\omega_b. \text{ Here we fix } \Delta_m = 1.7 \omega_b \text{ and } g = G = 0.1 \omega_b.\]

The effective Hamiltonian in the double-exciton subspace spanned by \( \{|002\}, |101\rangle, |200\rangle \} \), where the magnon remains at the ground mode, can be written as

\[
H_{\text{eff}}^{(2)} = \begin{bmatrix} 0 & \sqrt{2} \hat{G} & 0 \\ \sqrt{2} \hat{G} & 0 & \sqrt{2} \hat{G} \\ 0 & \sqrt{2} \hat{G} & 0 \end{bmatrix}, \tag{15}\]

\[\text{where } \hat{G} = \frac{Gg}{\omega_b - \Delta_m}.\]
whose eigenstructure is found to be
\[
\begin{aligned}
E_1 &= \sqrt{2}G, \quad |\Psi_1\rangle = \frac{|002\rangle + |200\rangle}{\sqrt{2}} + \frac{|101\rangle}{\sqrt{2}}, \\
E_2 &= -\sqrt{2}G, \quad |\Psi_2\rangle = \frac{|002\rangle + |200\rangle}{\sqrt{2}} - \frac{|101\rangle}{\sqrt{2}}, \\
E_3 &= 0, \quad |\Psi_3\rangle = \frac{|002\rangle - |200\rangle}{\sqrt{2}},
\end{aligned}
\] (16)
and the time-evolution operator reads
\[
U(t) = \frac{1}{2} \begin{pmatrix}
    c + 1 & -s\sqrt{2}i & c - 1 \\
    -s\sqrt{2}i & c & -s\sqrt{2}i \\
    c - 1 & -s\sqrt{2}i & c + 1
\end{pmatrix}
\] (17)
with \(c \equiv \cos(2\hat{G}t)\) and \(s \equiv \sin(2\hat{G}t)\). The energy diagram and the avoided level-crossing between |200⟩ and |002⟩ are plotted in Fig. 4. The conversion time is still \(\pi/2\hat{G}\). In addition, it is interesting to observe that the last eigenstate |Ψ3⟩ is a dark state in this specific case. The vanishing eigenvalue implies that this eigenstate will remain intact during the time evolution.

More versatile physics can be exploited in the subspace with more excitons, in which the magnon always stays as the vacuum state. For a fixed total number of photon and phonon \(N\), the effective Hamiltonian in Eq. (12) in the subspace spanned by \{|N00⟩, |(N − 1)01⟩, · · · , |10(N − 1)⟩, 00N⟩\} can be expressed by
\[
H_{\text{eff}}^{(N)} = \hat{G} \begin{pmatrix}
    0 & L_1 & 0 & \cdots & 0 \\
    L_1 & 0 & L_2 & \cdots & 0 \\
    0 & L_2 & 0 & \cdots & 0 \\
    \vdots & \vdots & \vdots & \ddots & \vdots \\
    0 & 0 & 0 & \cdots & L_{N-1}
\end{pmatrix},
\] (18)
where \(L_n = \sqrt{n(N − n)}\). It is interesting to be identical to the matrix representation of the Hamiltonian \(H = 2\hat{G}S_x\), where \(S_x\) is the angular momentum operator for a fictitious particle with spin \(S = \frac{1}{2}(N − 1)\). The Hamiltonian \(H_{\text{eff}}^{(N)}\) also describes an open-end spin chain governed by the site-dependent nearest-neighbor interactions [38]
\[
H_{\text{spin}} = \sum_n \frac{\hat{G}L_n}{2} (\sigma_n^x \sigma_{n+1}^x + \sigma_n^y \sigma_{n+1}^y),
\] (19)
which is used to realize a perfect state transfer through the chain. If the initial state is prepared as |N00⟩, then the probability amplitude for state transfer is
\[
A(t) = \langle 00N| \exp(-i2\hat{GS}_rt)|N00⟩ = [-\sin(\hat{G}t)]^{N-1}.
\] (20)
Therefore, the perfect conversion about a quantum state between photon and phonon is accomplished in a constant time \(\pi/(2\hat{G})\), irrespective to the exciton number or the particular subspace. Ideally, any superposed state of the photon can be converted into the phonon mode through the evolution time \(\pi/(2\hat{G})\).

![FIG. 5.](image)

**FIG. 5.** (Color online) (a) and (c) Comparison between the numerically calculated normalized effective coupling strength \(G/\omega_h\) (blue dots) and the corresponding analytical results in Eq. (9) for the second-order perturbation theory (orange solid lines) as functions of \(g/\omega_h\) and \(G/\omega_h\), respectively; (b) and (d) Comparison between the numerically calculated normalized energy shift \(\delta/\omega_h\) (blue dots) and the corresponding analytical results in Eq. (9) (orange solid lines) as functions of \(g/\omega_h\) and \(G/\omega_h\), respectively. For (a) and (b) \(G = 0.1\omega_h\), and for (c) and (d) \(g = 0.1\omega_h\). Here we fix \(\Delta_m = 1.7\omega_h\).

**III. THE APPLICATION RANGE OF THE EFFECTIVE HAMILTONIAN**

We first check the applicability range of the effective Hamiltonian in Eq. (12) in terms of the coupling strength. It can be estimated or constrained by comparing the numerical results obtained from the original Hamiltonian in Eq. (3) for the full Hilbert space and the analytical results obtained via the perturbative derivation for the reduced subspace. The energy-splitting \(|G|\) of the two eigenstates at the avoided level-crossing point (see Fig. 3 in the single-exciton case) is presented in Fig. 5(a) and (c) as a function of the original coupling strengths \(g\) and \(G\) in the interaction Hamiltonian, respectively. The result given by the analytical expression in Eq. (13) is compared to that evaluated by the numerical simulation over the whole Hilbert space. It is found that the effective coupling strength \(|G|\) is valid until \(g/\omega_h \approx 0.1\) and \(G/\omega_h \approx 0.1\). For a larger \(g\) or \(G\), higher-order contributions have to be included to capture the whole effect from the interaction Hamiltonian on modifying the eigenstructure of the bare system. However, an apparent yet still small deviation can be observed when either \(g\) or \(G\) is enhanced to 0.15\(\omega_h\). The effective Hamiltonian in Eq. (12) could therefore be used to investigate the effects in the strong-coupling regime.

Similarly, the energy shift \(\delta\) in Eq. (9) can also be justified by Fig. 5(b) and (d). We check the same range of \(g\) and \(G\) as in Fig. 5(a) and (c). It is shown that the analytical results do match with the numerical ones at least when the normalized photon-magnon interaction strength \(g/\omega_h \leq 0.15\) or phonon-magnon coupling strength \(G/\omega_h \leq 0.15\).
Next we take the open-quantum-system framework to further test the validness of the effective Hamiltonian in Eq. (12) in terms of the state-evolution fidelity. Under the standard assumptions (Markovian approximation, factorization of the system-environment density matrix, structure-free environment at the vacuum state), one can arrive at the Lindblad master equation for the density matrix of the interested hybrid-system,

$$
\dot{\rho}(t) = -i[H, \rho(t)] + \kappa_a \mathcal{L}[a] \rho(t) + \kappa_m \mathcal{L}[m] \rho(t) + \gamma_b \mathcal{L}[b] \rho(t).
$$

(21)

Here $H$ is the full Hamiltonian of the system given in Eq. (3), $\kappa_a$, $\kappa_m$ and $\gamma_b$ are the relaxation rates for cavity-mode, magnon and phonon, respectively, and the superoperator $\mathcal{L}[O]$, $O = a, m, b$, is defined as

$$
\mathcal{L}[O] \rho \equiv \frac{1}{2}(2 \mathcal{O}\rho \mathcal{O}^\dagger - \mathcal{O}^\dagger \mathcal{O}\rho - \rho \mathcal{O}^\dagger \mathcal{O}).
$$

(22)

While for the effective model constituted by the photon and the phonon in Eq. (12), the Lindblad equation in the reduced subspace is written as

$$
\dot{\rho}(t) = -i[H_{\text{eff}}, \rho(t)] + \kappa_a \mathcal{L}[a] \rho(t) + \gamma_a \mathcal{L}[b] \rho(t).
$$

(23)

To simplify the discussion but with no loss of generality, we assume the decay rates of the photon and the magnon are the same $\kappa_a = \kappa_m = \kappa$, and set the decay rate of phonon $\gamma_a = 10^{-2}\kappa$ regarding that the decoherence rates of phonon are much smaller than that of cavity-mode or magnon [20].

Then one can numerically calculate the state-fidelity $F_s = \langle \phi | \rho | \phi \rangle$, where $| \phi \rangle$ is the target state, under either equation (21) or equation (23). The distinction between the results from different master equation measures both the validness of the effective Hamiltonian and the robustness of our photon-phonon conversion protocol. In Fig. 6, we plot the state-fidelity dynamics under different decoherence rates when the initial state and the target state are chosen as $|001\rangle$ and $|\phi\rangle = |100\rangle$, respectively. The blue solid line and the yellow dot-dashed line are the results from Eq. (23) using the effective Hamiltonian, and the orange dashed line and the purple dotted line are those from Eq. (21) using the full Hamiltonian. It is found that the results using the full Hamiltonian have a slightly longer period than those using the effective Hamiltonian in time evolution. Yet they match almost with each other at least for the first two or three periods of Rabi oscillation. In case of no decoherence, the state-fidelity achieves over 0.97 by the full Hamiltonian. With the Markovian decoherence rate $\kappa = 10^{-3}\omega_b$, both master equations produce the desired target-state with a fidelity over 0.90 for photon-phonon conversion during the first period and maintain the target state with a fidelity about 0.85 during the third period.

IV. THE TRANSFER FIDELITY UNDER THE STRUCTURED ENVIRONMENTS

The phenomenological analysis on the Markovian errors on the state-fidelity depends on the choice of the initial state and the target state during the photon-phonon conversion. It is indispensable to discuss the relationship between the transfer-fidelity by the effective Hamiltonian, that is independent on the state, and the non-Markovian errors, that is ubiquitous in almost all of the solid state systems. In this section, we investigate the effect from the structured environment using the non-Markovian Heisenberg-Langevin equation [10, 14], by assuming that in a microscopic way the system is coupled to its environment consisted of a collection of independent harmonic oscillators. The total Hamiltonian reads,

$$
H_{\text{tot}} = H_{\text{eff}} + H_E + H_I.
$$

(24)

Here the environmental Hamiltonian for the photon-phonon system reads

$$
H_E = \sum_k \omega_k a_k^\dagger a_k + \sum_j \Omega_j b_j^\dagger b_j,
$$

(25)

where $\omega_k$ and $\Omega_j$ are the reservoir frequency for the $k$th optical and the $j$th mechanical mode respectively. The two reservoirs are assumed to be uncorrelated. The interaction between the system and the environment can then be described by

$$
H_I = \sum_k g_k (a_k^\dagger a + a^\dagger a_k) + \sum_j f_j (b_j^\dagger b + b^\dagger b_j),
$$

(26)

where $g_k$ and $f_j$ are the respective system-reservoir coupling strength for the optical mode and the mechanical mode [39] and supposed to be real numbers for simplicity. Here the interaction Hamiltonian is written in a form under the rotating-wave approximation, which is valid when the coupling strength is much smaller than the resonant frequency of the system, i.e., $g_k, f_j \ll \omega_b, \Delta_a$.

With the effective Hamiltonian for the system part in Eq. (12) and the interaction Hamiltonian in Eq. (26),
one can write down the Heisenberg-Langevin equations in the rotating frame with respect to the environmental Hamiltonian in Eq. (25),
\[ \dot{O}(t) = -iMO(t) - \int_0^t d\tau \dot{F}(t - \tau)O(\tau) + \epsilon_{in}(t). \] (27)

Here the time-evolution operator for the system modes is \( O(t) = \begin{bmatrix} a(t), b(t) \end{bmatrix}^T \) and the input noise operator is \( \epsilon_{in}(t) = \begin{bmatrix} \epsilon_{in}(t), b_{in}(t) \end{bmatrix}^T \), where \( \epsilon_{in} \equiv -i \sum k g_k e^{-i\omega_k t} a_k(0) \) and \( b_{in} \equiv -i \sum f_j e^{-i\beta_j t} b_j(0) \) depend on the initial condition of the environment. The thermal average occupation numbers in the particular modes of the two reservoirs are \( \bar{n}_a(\omega_k) \equiv \langle a_k^\dagger(0) a_k(0) \rangle = 1/\exp(h \omega_k/k_B T_a) - 1/\delta_{k_k} \) and \( \bar{n}_b(\omega_j) \equiv \langle b_j^\dagger(0) b_j(0) \rangle = 1/\exp(h \omega_j/k_B T_b) - 1/\delta_{j j} \), respectively. The coefficient matrix \( M \) and \( \tilde{F}(t) \) are given by
\[ M = \begin{bmatrix} 0 & G \\ G & 0 \end{bmatrix}, \quad \tilde{F}(t) = \begin{bmatrix} f_a(t) & 0 \\ 0 & f_b(t) \end{bmatrix}, \] (28)
respectively, where \( f_a(t) \equiv \sum_k g_k^2 e^{-i\omega_k t} \) and \( f_b(t) \equiv \sum_j f_j^2 e^{-i\beta_j t} \) are the non-local time correlation functions.

We can rewrite the correlation functions by introducing the spectral density functions
\[ f_x(t) = \int d\omega J_x(\omega) e^{-i\omega t}, \quad x = a, b \] (29)
for the optical and the mechanical environments, respectively. The environment for the cavity mode is generally of an Ohmic-like spectrum, i.e., \( J_a(\omega) = \eta \omega(\omega/\omega_0)^{s-1}e^{-\omega/\omega_0} \), where \( \eta \) is a dimensionless coupling strength between system and environment, and \( \omega_0 \) is a high-frequency cutoff [40]. The parameter \( s \) classifies the environment as sub-Ohmic (\( 0 < s < 1 \)), Ohmic (\( s = 1 \)), or super-Ohmic (\( s > 1 \)). For the phonon mode in the YIG sphere, the solid-state environment is assumed to be a 1/f-like spectrum, similar to that for the optomechanical system recently measured in experiments. We therefore use the spectral density function \( J_b(\omega) = \bar{C} \omega^k \), where the coupling coefficient \( C > 0 \), \( k \) is a negative number around \(-1 \) [41] and the bandwidth in this work is chosen as \( \omega \in [0.1 \omega_0, 2 \omega_0] \).

Formally, Eq. (27) can be solved by assuming \( O(t) = \hat{U}(t)O(0) + \hat{V}(t) \), where \( \hat{U}(t) \) is a \( 2 \times 2 \) coefficient matrix \( [\hat{U}_{11}(t), \hat{U}_{12}(t); \hat{U}_{21}(t), \hat{U}_{22}(t)]^T \) as a function of time, and \( \hat{V}(t) \) is a vector of operators \( [\hat{V}_1(t), \hat{V}_2(t)]^T \) related to the nonequilibrium Green’s functions of the system. These Green’s functions obey the following Dyson equations
\[ \dot{\hat{U}}(t) = -iM \hat{U}(t) - \int_0^t d\tau \dot{\hat{F}}(t - \tau)\hat{U}(\tau), \] (30)
\[ \dot{\hat{V}}(t) = -iM \hat{V}(t) - \int_0^t d\tau \dot{\hat{F}}(t - \tau)\hat{V}(\tau) + \epsilon_{in}(t). \]

Considering the initial conditions \( \hat{U}(0) = I \) and \( \hat{V}(0) = 0 \), one can formally have
\[ \hat{V}(t) = \int_0^t d\tau \hat{U}(t - \tau)\epsilon_{in}(\tau). \] (31)

With the solution about \( \hat{U}(t) \), the dynamical evolution of \( b(t) \) is written as
\[ b(t) = U_{21}(t)a(0) + U_{22}(t)b(0) + \hat{V}_2(t). \] (32)

Then the expectation value of the phonon number \( \langle b(t)b(t) \rangle \) can be evaluated by
\[ \langle b(t)b(t) \rangle = \langle U_{21}(t)^2 \rangle \langle a(0)b(0) \rangle + \langle U_{22}(t)^2 \rangle \langle b(0)b(0) \rangle \] (33)

The first term on the right-hand side of Eq. (33) is proportional to the initial average number of photon \( \langle a^\dagger(0)a(0) \rangle \). The second term is proportional to the initial average number of phonon \( \langle b^\dagger(0)b(0) \rangle \), whose contribution could be reduced by pre-cooling the mechanical oscillator to the ground state. As for the last term, one can express it by
\[ \langle \hat{V}_2^\dagger \hat{V}_2 \rangle = \int \frac{d\omega}{2\pi} J_a(\omega) \bar{n}_a(\omega) \int_0^t U_{21}(t - \tau)e^{-i\omega\tau} \] (34)
\[ + \int \frac{d\omega}{2\pi} J_b(\omega) \bar{n}_b(\omega) \int_0^t U_{22}(t - \tau)e^{-i\omega\tau} \] (35)

Assume the environmental temperature for the photon mode \( T_a \approx 0 \) and the bandwidth of the spectral density for the mechanical environment is sufficiently narrow around the resonant frequency, the average value \( \langle \hat{V}_2^\dagger \hat{V}_2 \rangle \) is upper-bounded by \( \bar{n}_b(\omega_b) \| \hat{V}_2^\dagger \hat{V}_2 \|_2 \) due to the fact that
\[ \| \hat{V}_2 \|_2 = \int \frac{d\omega}{2\pi} J_a(\omega) \int_0^t U_{21}(t - \tau)e^{-i\omega\tau} \] (36)
\[ + \int \frac{d\omega}{2\pi} J_b(\omega) \int_0^t U_{22}(t - \tau)e^{-i\omega\tau} \] (37)

Also note the commutation relation \( [b(t), b^\dagger(t)] = 1 \) holds for any moment \( t \), which renders
\[ \| U_{21} \|^2 + \| U_{22} \|^2 + \| \hat{V}_2^\dagger \hat{V}_2 \|^2 = 1. \] (38)

Apparently \( \langle \hat{V}_2^\dagger \hat{V}_2 \|^2 \geq 0 \). It means that under a low temperature \( T_b \), both \( \| U_{22} \| \) and \( \| \hat{V}_2^\dagger \hat{V}_2 \| \) are close to zero when \( \| U_{21} \| \approx 1 \). We therefore understand that the transfer fidelity \( F \) from photon to phonon can be quantified by \( \| U_{21}(t) \| \) [14] using the numerical solution of Eq. (30). Since this fidelity is obtained in the Heisenberg picture, it is then independent of the initial and target states.

We first comparing the noise effects on \( F \) from various combinations of the structured and the Markovian environments for the photon and phonon modes as shown in Fig. 7. The structured environments are characterized by their spectral functions and the Markovian environments are characterized by their decay constants, which are obtained under the Weisskopf-Wigner approximation. In particularly, the optical-mode decay rate is \( \kappa_a = J_a(\omega_a)/2 \) and the mechanical-mode decay rate is \( \gamma_b = J_b(\omega_b)/2 \). When both modes are embedded in the
realistic structured environments (see the blue-solid line), the conversion fidelity is close to 0.98 in the first period of Rabi oscillation and could be still maintained above 0.9 in the third period. It is nearly invariant when the environment for the phonon mode is changed to be a Markovian type (see the yellow-dotted line). The conversion will be greatly damaged when the photon mode is subject to a Markovian type and in this case, it is also insensitive to the choice of the phonon-mode environment (see the red-dashed purple-dotted lines). In both cases, the conversion fidelity is no more than 0.35 and could not start a second period of Rabi oscillation. These results indicate that the non-Markovian noise from the structured environment for the photon mode is more significant than that for the phonon mode on protecting the conversion fidelity.

In Fig. 8, the phonon mode is subjected to a fixed 1/f noise with \( k = -1 \) and then one can observe the effects from the sub-Ohmic \((s = 0.5)\), Ohmic \((s = 1)\), and super-Ohmic \((s = 2)\) environments for the photon mode on the time evolution of the transfer fidelity. The other parameters of these power-law noises are fixed. We can see that the sub-Ohmic spectrum and the Ohmic spectrum are better than the super-Ohmic spectrum in terms of conversion fidelity. For the sub-Ohmic spectrum, the fidelity could be close to 0.99 during the first period of Rabi oscillation and still around 0.90 during the third period. These results are close to those for the Ohmic spectrum. While the fidelity will drop to about 0.80 during the third period of Rabi oscillation for the super-Ohmic spectrum.

In Fig. 9, one can observe that the conversion fidelity is also insensitive to different choice of the structured environments for the phonon mode. Under a fixed Ohmic environment for the photon mode, the conversion fidelity shows a slightly decreasing pattern with increasing \(|k|\). Thus in realistic situations, the conversion process between the photon mode and the phonon mode is strongly resilient to the 1/f-type noise for the phonon mode.

V. DISCUSSION AND CONCLUSION

When the yttrium iron garnet sphere are strongly pumped to generate a considerable number of magnons, the Kerr effect due to the ensuing magnetocrystalline anisotropy could not be completely neglected. Considering that the exciton number in the spin wave is much smaller than the total number of spins in YIG sphere, one can modify the system Hamiltonian in Eq. (1) to be [42, 43],

\[
\hat{H}_S = H_S + Km^\dagger mm^\dagger m, \tag{37}
\]

where \( K \) is the nonlinear coefficient for the Kerr effect. With the linear approximation, the Kerr term...
$K^m m^m m$ becomes $2K \langle m^m m \rangle m^m m$, thus the Hamiltonian $H_0$ in Eq. (3) turns out to be

$$\tilde{H}_0 = \Delta_a a^\dagger a + \tilde{\Delta}_m m^\dagger m + \omega_b b^\dagger b,$$

(38)

where $\tilde{\Delta}_m = \Delta_m + 2K \langle m^m m \rangle$ [44]. Then the derivation process for the effective Hamiltonian describing the photon-phonon conversion [from Eq. (3) to Eq. (12)] would be merely modified in quantity to ensure that the frequency detuning of the magnon-mode approaches the frequency of the cavity-mode. The Kerr term will eventually only change the effective coupling strength $G$ in Eq. (13). For a YIG sphere with a diameter about 250$\mu$m, the Kerr coefficient $K/2\pi \approx 6.4 \times 10^{-3}$Hz and the magnon exciton number $\langle m^m m \rangle \approx 10^{14}$ corresponding to $G = M g_n b \sim 10^7$Hz via $M = \sqrt{\langle m^m m \rangle}$. Then one can estimate that $K \approx 10^5$Hz, which is much smaller than $\Delta_m$. It is therefore believed that our proposal also adapts to such a hybrid system even with a non-negligible Kerr effect.

In summary, we have presented a protocol to realize a photon-phonon interface or conversion in a cavity magnomechanical system, where the magnon mode in the YIG sphere is coupled to both a microwave cavity mode and the mechanical vibration mode in the same sphere. Our magnon-assisted protocol relies on the effective Hamiltonian coupling photon and phonon, which is constructed in the strong coupling regimes for both magnon-photon interaction and magnon-phonon interaction without applying the adiabatic elimination method. In the open-quantum-system framework, the state fidelity of the photon-phonon conversion is mainly limited by the decay of the microwave cavity $\kappa_a$ rather than the dissipation of the phonons $\gamma_b$, due to the fact that $\gamma_b$ is much smaller than the phonon frequency $\omega_b$ [20]. We also analyze the effect from various environmental noises on the conversion fidelity using the non-Markovian Heisenberg-Langevin equations. Excellent results can be obtained when the cavity mode is under a structured environment with sub-Ohmic spectrum even if the phonons are in a Markovian environment. Our work in pursuit of the quantum state transfer and protection therefore provides a novel implementation of the photon-phonon interface realized in a solid system under realistic noises. It also extends the application range of the cavity-magnomechanical system as a hybrid platform for quantum information processing.
