INTRODUCTION

The vast majority of research on emerging antibiotic resistance (AR) has focused on AR in clinical settings. However, there is growing recognition that resistance acquired outside of hospital settings (community-acquired infections) is a serious and growing threat (Pitout et al., 2005). Antibiotics are likely important for bacterial interactions in natural communities as resistance genes originated in environmental bacteria long before the antibiotic era (Aminov and Mackie, 2007; Martinez, 2008; Davies and Davies, 2010). The collection of all resistance genes and their precursors in pathogenic and non-pathogenic microorganisms has been termed the antibiotic “resistome” (Wright, 2007).

Bacteria can readily exchange DNA via lateral transfer of mobile genetic elements (e.g., plasmids or transposons). Thus, AR genes from non-pathogenic environmental microorganisms have the potential to be transferred to pathogens infecting humans, especially when use of antibiotics imposes heavy selective pressure. Indeed, as a result of widespread antibiotic use in medicine and agriculture, multidrug resistant bacteria and resistance genes have been detected in many environments (e.g., Sayah et al., 2005; Seyfried et al., 2010). Antibiotics and AR bacteria originating from human-made AR “reservoirs” may be released into nearby groundwater, streams, rivers, and estuaries (Li et al., 2009; Martinez, 2009), potentially leading to emergence of novel mechanisms of resistance in pathogenic organisms. However, discovery of new AR mechanisms is limited because most studies focus on culturable bacteria and known genes detected via PCR. This approach has resulted in a heavily biased and incomplete understanding of the broader environmental resistome.

Wildlife may facilitate the spread of antibiotic resistance (AR) between human-dominated habitats and the surrounding environment. Here, we use functional metagenomics to survey the diversity and genomic context of AR genes in gulls. Using this approach, we found a variety of AR genes not previously detected in gulls and wildlife, including class A and β-lactamases as well as six tetracycline resistance gene types. An analysis of the flanking sequences indicates that most of these genes are present in Enterobacteriaceae and various Gram-positive bacteria. In addition to finding known gene types, we detected 31 previously undescribed AR genes. These undescribed genes include one most similar to an uncharacterized gene in Verrucomicrobiunum and another to a putative DNA repair protein in Lactobacillus. Overall, the study more than doubled the number of clinically relevant AR gene types known to be carried by gulls or by wildlife in general. Together with the propensity of gulls to visit human-dominated habitats, this high diversity of AR gene types suggests that gulls could facilitate the spread of AR.

Keywords: herring gulls, antibiotic resistance, Verrucomicrobia, Larus argentatus, metagenomics

Wildlife may facilitate exchange of AR bacteria and genes between human-made and natural environments. AR bacteria and, more recently, AR genes have been detected in a variety of wild birds and mammals (e.g., Mallon et al., 2002; Literak et al., 2009; Marrow et al., 2009). Many species of wildlife visit human-made areas such as farms and sewage lagoons where they may acquire AR (Osterblad et al., 2001; Blanco et al., 2009). Further, some studies have discovered high abundances of AR bacteria in wildlife with little or no apparent exposure to anthropogenic sources (Williams et al., 2011).

Gulls may be a particularly important carrier of AR because of their close association with humans. During the past several decades, gull populations have increased worldwide due in large part to burgeoning human populations along coasts and the associated increase in availability of human-derived foods (Duhem et al., 2008; Schwemmer et al., 2008). Gulls carry a diverse array of potentially pathogenic bacteria including Salmonella spp., (Skov et al., 2008), Campylobacter spp. (Waldenstrom et al., 2007), Listeria spp. (Fenlon, 1985), and vero cytotoxin-producing Escherichia coli O157 (Wallace et al., 1997), which they likely acquire by feeding and loafing at sewage lagoons, garbage dumps, and farms (Benskin et al., 2009). Moreover, several recent studies have detected clinically relevant AR bacteria (Cizek et al., 2007; Rose et al., 2009) and AR genes (e.g., Dolejska et al., 2007; Bonnedahl et al., 2010) in gull feces.

Here, we use functional metagenomics to characterize the diversity of the gull resistome. Previous studies of AR genes in gulls and other wildlife have relied on initial cultivation of bacteria or PCR of specific, known gene variants. However, studies using functional
metagenomics have revealed a diverse array of previously undescribed AR genes in soils (Rondon et al., 2000) and humans (Diaz-Torres et al., 2006; Sommers et al., 2009). We assay: (1) the most abundant AR classes and gene types within these classes that confer resistance to four antibiotics; (2) information about the genes’ genomic context (i.e., the genomic neighborhood) as revealed by the flanking sequences; and (3) microdiversity within the abundant gene types. Specifically, we screened the libraries for resistance against ampicillin, amoxicillin, penicillin, and tetracycline. These four antibiotics were chosen due their historical importance, differences in resistance mechanism, and range of target organisms. Penicillin, ampicillin, and amoxicillin are β-lactam antibiotics. In the past 20 years, bacterial strains that produced extended-spectrum β-lactamases (ESBLs) – enzymes conferring broad resistance to β-lactam antibiotics – have emerged posing a major threat to public health (Pitout and Laupland, 2008). Tetracyclines have been used for more than 40 years in clinical and agricultural settings and are broad-spectrum agents, exhibiting activity against a wide range of organisms (Chopra and Roberts, 2001). Resistance to tetracyclines is also widespread in the environment (e.g., Nascimento et al., 2003; Bryan et al., 2004).

MATERIALS AND METHODS

SAMPLING

Fecal samples were collected from four Herring Gulls in a breeding colony at the Shoals Marine Laboratory on Appledore Island, ME (42° 58′ N, 70° 36′ W) located approximately 10 km off the coast of mainland United States. Approximately 650 pairs of Herring Gulls nest on the island (Ellis, unpublished data). We collected fresh samples by observing individual birds until defecation occurred and immediately collecting samples from the ground using a sterile syringe. For comparison, one soil and two gull samples were also collected from the mainland (Rochester, NH, USA). Samples were immediately placed on ice. DNA extraction was performed with the FastDNA Spin for Soil kit (MP Biomedical, CA, USA) using the protocol of the manufacturer with the following changes. Cells were lysed using the MP Biomedicals FastPrep24 (setting 5.0 twice for 45 s and once for 20 s, cooling on ice in between). The precipitation step was carried out twice with 250 μl protein precipitation solution (PPS) from the FastDNA Spin for Soil kit (MP Biomedical, CA, USA). We used 1.5 ml binding matrix and inverted for 4 min. We discarded 1 ml of the supernatant. The final pellet was resuspended in 75 μl of the provided water.

CLONING AND SCREENING

Three micrograms of genomic DNA from gull feces was sheared to a target size of 3 kb with a Covaris S2 instrument (Covaris Inc., MA, USA). The 3-kb fragments were end-repaired with the DNA Terminator End Repair kit (Lucigen, WI, USA). The DNA was loaded on a 1% low melt agarose gel and fragments between 1 and 3 kb were extracted with Zymoclean Gel Recovery kit (Zymoclean Research, CA, USA). DNA was eluted in 10 μl TE elution buffer and ligated into pSMART–Hckan vector (accession number AF532107) using the Clonesmart blunt end cloning kit (Lucigen, WI, USA). Ligation was carried out overnight at room temperature. E. coli 10G electrocompetent cells (Lucigen, WI, USA) were transformed by electroporation using a BTX electroporator and 1.0 mm gap cuvettes.

Electroporation conditions were 25 μF, 200 Ω, and 1800 V. The transformation was incubated for 1 h at 37°C and, after adding 30 μg/ml kanamycin, the transformation mixture was incubated another 2 h at 37°C. We plated 0.1 μl of the transformation mixture on kanamycin LB plates for titer counts and 100–200 μl on ampicillin (50 μg/ml), amoxicillin (20 μg/ml), penicillin (50 μg/ml), and tetracycline (8 μg/ml) containing plates. Screened clones were picked and grown up overnight without shaking in LB + 10% glycerol. Sequencing was done using the SL1 forward primer (5′-CAGTCAGGTATGATTTAAATGGTCAGT-3′) and SR2 reverse primer (5′-GGTCAGGTATGATTTAATGGTCAGT-3′; as suggested by Lucigen) and sequenced at Beckman Coulter Genomics.

MINIMAL INHIBITORY CONCENTRATION

Antibiotic resistance clones were tested in duplicate for growth in the following concentrations of ampicillin: 60, 100, 200, 350, 500, 800, and 1000 μg/ml. Five microliters of live culture was inoculated into 96-well plates containing 225 μl LB Broth plus kanamycin (30 μg/ml) and the above concentrations of ampicillin. We also included a “no-cell” control for contamination and background OD. The cultures were incubated at 37°C and growth was measured at OD600 every 15 min for 24 h.

Tn5 TRANSPOSON “KNOCKOUT” OF AR GENES

To identify the AR gene in selected inserts, we randomly inserted a Tn5 transposon in the clones using the EZ-TN5 <TET-1> Insertion Kit (Epicentre, CA, USA). We used a molar ratio Tn5 to AR plasmid of one to minimize multiple insertion events. One microliter of a transposon reaction was electroporated (BioRad BTX) into 50 μl of E. Cloni 10G Electrocompetent Cells (Lucigen). Cells were plated on LB Agar containing kanamycin (30 μg/ml) and tetracycline (10 μg/ml). Colonies were next screened for Tn5 “knockouts” based on lack of ampicillin resistance in LB Broth plus kanamycin (30 μg/ml), tetracycline (10 μg/ml), and ampicillin (60 μg/ml). A replicate control 96-plate was also inoculated with the same colony in LB Broth plus kanamycin (30 μg/ml) and tetracycline (10 μg/ml). Both plates were grown at 37°C (without shaking) overnight. Sequencing was done using the TNS <TET-1> forward and reverse primers (provided in Epicentre kit).

SEQUENCE ANALYSIS

We trimmed the paired-end sequences using Phrap and analyzed the inserts using blast against both GenBank nr and the Antibiotic Resistance Genes Database (ARDB; Liu and Pop, 2009). For β-lactamases, the ARDB classification scheme generally follows other systems for organizing resistance genes (Bush and Jacoby, 2010). However, here we rely entirely on a sequence-based comparison. Using ARDB, genes are divided into the four major β-lactamase classes (A–D), then into specific ARDB types, and finally into sequence variants within each type. We detected some sequences that were identical to β-lactamases used in common cloning vectors; because we cannot determine whether these sequences are contaminants we removed them from the analysis.

Sequences from each ARDB type were assembled into contigs using Geneious (Biomatters). For selected inserts, we aligned and translated the sequences and built phylogenetic trees with Phylip (100 bootstraps) using neighbor-joining (protein distance
matrix with Jones–Taylor–Thornton correction) and maximum likelihood methods (Jones–Taylor–Thornton correction and constant rate of change among sites; Felsenstein, 2006). The phylogenetic trees were visualized with the Interactive Tree of Life (iTOL, http://itol.embl.de/index.shtml; Letunic and Bork, 2007). Sequences from this study have been submitted to GenBank under accession numbers JM426721–JM427844.

RESULTS

AR GENE DIVERSITY

To target AR in gulls, we sampled feces from four gulls on Apple-dore Island, Maine, and two gulls in Rochester, NH, USA. For comparison, we also sampled soil in Rochester without any gulls nearby (Table 1). We extracted and sheared the DNA, then cloned 3 kbp DNA fragments into E. coli. The number of resulting clones ranged between $1 \times 10^5$ and $4.4 \times 10^6$ per library. Based on these numbers, we estimate that up to 5% of the bacteria in gull feces are resistant to antibiotics (Table 1). We found ampicillin, amoxicillin, and penicillin resistance genes in all gulls assayed, whereas we detected tetracycline AR genes in only two out of six gulls. Although it is difficult to compare across antibiotics due to differences in potency and concentration, resistance to ampicillin was found in higher occurrence than amoxicillin and penicillin.

Gulls carried an extensive genetic diversity of both known and previously undescribed AR genes. To characterize this diversity in the metagenomic libraries, we paired-end sequenced the resistant clones and first classified the genes using ARDB (Liu and Pop, 2009; Tables 2 and 3). Overall, we found that similar genes conferred resistance to ampicillin, amoxicillin, and penicillin, including nine different class A and C β-lactamase ARDB categories. The most common category was bl1_ec, which was 100% similar to a β-lactamase in E. coli strain 1.1.43. Another common category detected was the extended-spectrum class A β-lactamase (ARDB category: bl2b_tem1). However, the bl2b_tem1 types were not identical to known variants in the database and on average shared only 92% sequence similarity. Combined, these two ARDB categories constituted more than 50% of the AR clones (Table 2). The last common ARDB category was the class A CTX-M type. However, these genes only shared 72% amino acid sequence similarity to CTX-M genes in E. coli (Table 3). A broader search in GenBank and a phylogenetic analysis revealed that the gene was 100% similar to the β-lactamase variant RAHN-2 in the Gram-negative enteric bacterium Rahnella aquatilis Y9602 (Ruimy et al., 2010) and therefore, was likely not a CTX-M variant (Figure 1).

Beyond the class A and class C β-lactamases, we also found ampicillin- and penicillin-resistant clones encoding for efflux

Table 1 | Metagenomic sample overview, including a list of sample IDs and description, titer of each clone library, and the number of positive (resistant) clones to each antibiotic.

| Sample id | Location       | Environment  | Antibiotic | Total titer | + Clones | % AR cells |
|-----------|----------------|--------------|------------|-------------|----------|------------|
| 10-126    | Appledore      | Gull feces   | Ampicillin | $3.7 \times 10^6$ | 72        | 3.9        |

N is the number of libraries screened.

1These two columns indicate whether the AR gene type has previously been detected in either gulls or wildlife in general. This is based on the followed studies: Costa et al. (2006, 2008), Dolejska et al. (2007), Bonnedahl et al. (2009, 2010), Drobnic et al. (2009), Figueiredo et al. (2009), Jeters et al. (2009), Literak et al. (2009), Hernandez et al. (2010), Radhouani et al. (2010), Rybanova et al. (2010), Silva et al. (2010), Simoes et al. (2010), Ahmad et al. (2011), Alroy and Ellis (2011).

2The Rahnella variant has not been observed in gulls or wildlife before.

pumps (acrA and macB type) and a membrane carboxypeptidase (ARDB category: pbp1a). Finally, we observed a high proportion of clones (38%) that had no clear match in ARDB.

The tetracycline resistant genes detected belonged to several ARDB categories including tetC, tetJ, and tetL. Efflux pumps and tetM, tetO, and tetW ribosomal modification proteins. These genes were generally very similar to known genes (Table 3) and likely do not constitute new variants.

For comparison, we also analyzed the genetic diversity of AR in a nearby soil sample. Keeping in mind that we only analyzed one soil sample, we found a lower frequency of AR genes in the soil sample compared to the gulls. With the exception of tetW, all ARDB categories observed in soil were also detected in gulls. Furthermore, we did not detect the RAHN-2/CTX-M category in soil sample compared to the gulls. With the exception of one soil sample, we found a lower frequency of AR genes in the soil (and vice-versa), with perhaps some exceptions.

**GENOMIC NEIGHBORHOOD**

Antibiotic resistance genes are known to move around between hosts via lateral gene transfer, thus the AR gene sequence itself is not a good indicator of the organism with the gene. Therefore, we analyzed the flanking sequences around the AR genes (Figure 2; Tables 2 and 3). Data regarding the genomic neighborhood can give information about the host organism and/or whether the gene was located on a mobile genetic element. Our attempts to assemble clones belonging to the same ARDB category yielded good contigs, indicating that the detected AR genes shared flanking sequences.

An example of that was the common class C β-lactamase belonging to the ARDB category bl1_ec. All clones associated with this category were located on a genomic fragment syntenous with *E. coli* strain K-12 substr. DH10B and several other *E. coli* strains (Figure 2A). Similar to DH10B, the gene was flanked by fumarate reductase subunits fnbD, fnbC, and fnbD, an outer membrane lipoprotein (BIC), a quaternary ammonium compound-resistance protein (segE), and the toxin entericidin (Durfee et al., 2008). Overall, this suggests that the most common class C β-lactamase found in the gulls was located on a genomic fragment similar to that found in *E. coli*. Similarly, the β-lactamase variant RAHN-2 also assembled into one contig which suggested a fragment syntenous with the genome from *R. aquatilis* Y9602 (Figure 2B). This contig including a chemotaxis gene and a hypothetical protein. This supports the hypothesis that this variant is indeed located in a *Rahnella* genome.

In contrast to the bl1_ec and RAHN-2 variants, clones matching the TEM class A β-lactamases (bl2b_tem1) were found in a range of genetic neighborhoods. The genes flanking bl2b_tem1 sequences were in some cases most closely related to Gram-positive bacteria (e.g., *Lactobacillus, Enterococcus*, and *Clostridium*) and in other cases, to Gram-negative bacteria (e.g., *E. coli*, *Shigella*, and *Salmonella*).

There were two major types of tetracycline resistance genes in our samples – efflux pumps (tetC, tetJ, and tetL) and ribosomal modification proteins (tetM, tetO, and tetW; Table 2). With the exception of tetJ, these were all associated with Gram-positive bacteria including *Bacillus, Enterococcus*, and *Clostridium*. Some of them were located on what appeared to be mobile elements including plasmids and transposons.

**AR GENE MICRODIVERSITY**

In addition to detecting multiple classes of AR genes, we found several DNA polymorphisms in the bl1_ec type. To further explore this result, we aligned the sequences matching this ARDB type and built a phylogenetic tree (Figure 3). All gull bl1_ec sequences grouped with *E. coli* 1.1.43 with high bootstrap support. In contrast, sequences retrieved from the soil samples formed three separate clades, with only one soil clone clustering with the gull variants. Instead, the one clade of soil AR sequences were 100% similar to *E. coli* H120, whereas the other genes branched away from known *E. coli* genes. Overall, this indicates that the bl1_ec diversity is related to its environmental origin. We also analyzed the sequence variation among clones from the RAHN-2 β-lactamase genes but only observed one variant.

**CHARACTERIZATION OF UNDESCRIBED AR GENES**

In addition to the known AR gene categories in ARDB, we detected 31 gene types not previously described (Table 3). The
novel AR genes were associated with a wide range of phylogenetic lineages including *Pseudomonas*, *Bacteroides*, Gram-positives, *Verrucomicrobia*, and different genera affiliated with *Enterobacteriaceae*. To further characterize these, we first measured the minimum inhibitory concentration (MIC) for ampicillin. All ampicillin/penicillin/amoxicillin resistant clones had an MIC above 1000 μg/ml ampicillin and thus clearly conferred resistance to this antibiotic.

Two of these clones assembled to a 2800-bp DNA fragment (unk15 in Table 3). One end of the fragment shared 84% amino acid similarity to the hypothetical protein VspiID_21980 in *Verrucomicrobiurn spinosum* from the phylum *Verrucomicrobia*. The other part of the fragment was 45% similar to a C-terminal protease in *Gemmata obscuriglobus* from the phylum Planctomycetes.

We next identified the genomic region in the clone that encoded for AR by randomly inserting a Tn5 transposon followed by testing for ampicillin resistance and DNA sequencing of the clones. The Tn5 “knockout” revealed that insertions in both genes interrupted the resistance whereas several insertions between the two genes had no effect. This represents a completely novel AR gene system that confers resistance in *E. coli*, but at present, we do not know the specific mechanism. To the best of our knowledge, this is the first study to identify an AR gene in either the phylum *Verrucomicrobia* or Planctomycetes.

A second previously uncharacterized AR gene (unk1) shared 85% amino acid similarity to a protein in the Gram-positive *Carnobacterium* sp. AT7 that was annotated as a putative DNA repair protein. A Tn5 insertion in this gene interrupted the resistance. Next to this putative AR gene was a gene 85% similar to *pilG* in another Gram-positive lineage, *Enterococcus faecalis*. Another previous unrecognized AR gene (unk31) was 92% similar to a DNA repair gene of the ImpB/MucB/SamB family in *Clostridium* sp. AT7 that was annotated as a putative DNA repair protein. A Tn5 insertion in this gene also interrupted the resistance. None of these DNA repair genes have previously been shown to confer AR, so the exact mechanism of resistance is unclear.

**DISCUSSION**

Using a functional metagenomics approach, we detected an extensive diversity of AR genes in gulls, including both well-known and undescribed AR genes. Less than half of the gene types detected have been reported previously in gulls (Table 2). We also detected several completely unknown AR genes including one associated with the lesser-known phyla *Verrucomicrobia* and *Planctomycetes*. These results highlight the strength of the functional metagenomic approach: the ability to reveal the most abundant genes conferring resistance to a particular antibiotic, without requiring prior knowledge of the gene classes of interest. In contrast, most studies of antimicrobial resistance have used PCR to characterize specific AR genes, often known from clinically relevant bacterial isolates (such as, *E. coli*, *Salmonella*, *Enterococcus* spp. – see references in Table 2). Our results suggest that these previous studies, while useful, may impart a heavily biased view of the AR genes carried by wild animals.

The functional metagenomic approach also has several advantages over a straight sequencing-based metagenomic analysis of a community. By including a functional screening, we can identify previously unknown AR genes that we would not have been able to identify by sequence homology searches (e.g., Sommer et al., 2009). Further, most metagenomic analyses only target the most abundant lineages, whereas the functional metagenomic approach allows for screening even rare members in the community.

Of course, there are limitations to the method used here. The approach is unlikely to detect mechanisms that require large (>3 kb) gene cassettes or that confer resistance by modifying regulation of genes in another genomic region (Viveiros et al., 2007). Further, it will only find AR genes that confer resistance in *E. coli*. Nonetheless, 42% of the gene types we detected originated from Gram-positive hosts (e.g., *Enterococcus* and *Clostridium*) as well as lesser-studied phyla like *Verrucomicrobiurn* and *Bacteroidetes*. This indicates that this bias may not be as dramatic as would be expected. Further, the functional assay yields the additional useful information that the genes are expressed in *E. coli* and therefore have the potential to be transferred and functional in human pathogens.

Wild animals are probably natural reservoirs of AR bacteria and genes, carrying them as part of their commensal flora (Wright, 2010). Alternatively, animals may acquire AR genes through exposure to human activities, including agriculture and animal husbandry (Osterblad et al., 2001). Without a much broader understanding of natural AR gene diversity, we cannot determine the source of AR genes in gulls. However, the gulls sampled in this study carried a variety of AR genes that are commonly found in bacteria isolated from humans and domestic animals. This
Martiny et al. Antibiotic resistance in gulls

FIGURE 3 | Phylogenetic tree of the bl1_ec type class C β-lactamase gene from metagenomic clones and sequenced representative strains from ARDB. The sequenced clones are from samples from gulls or soil, whereas we did not detect any bl1_ec type clones in samples from wastewater. Metagenomic clones were isolated on ampicillin, amoxicillin, or penicillin as listed for each entry. The phylogenetic tree is a majority rule consensus tree based on protein similarity using neighbor-joining. Bootstrap values (total 100) are calculated with neighbor-joining and maximum likelihood methods. Edwardsiella tarda sp. EIB202 is the outgroup.

result, similar to that of other recent studies of gulls and other wildlife, suggests that AR genes arising from the use of antibiotics in humans and animals may have spread to wildlife. The genes may then be further disseminated by wild animals, particular those that migrate long distances such as birds (Sjolund et al., 2008; Drobni et al., 2009).

Studies of gull ecology conducted at Appledore Island, Maine (where most of our samples were taken) indicate that gulls not only carry AR genes, but also have the potential to be a vector of the genes between human-dominated habitats and the environment. Appledore-banded gulls have been found at a variety of human habitats across New England and as far away as Florida (Ellis, unpublished data). They have been observed loafing at landfills and wastewater treatment plants and share strains of E. coli in common with wastewater from these sites (Nelson et al., 2008). Garbage brought back from the mainland is also a large part of the diet of gulls on Appledore Island (Ellis et al., 2005). Finally, the birds are frequently observed at public beaches in coastal New Hampshire and Maine during the summer, where they come into close contact with humans. Thus, the combination of the traveling patterns of gulls and the extensive diversity of AR genes that they carry suggest that gulls may be important vectors for spreading AR genes in areas where humans live.

The most common gene detected in our study was bl1_ec, a class C β-lactamase. The microdiversity within this gene type provides further evidence that gulls could move AR genes from human habitats to the environment. The gull variants were highly similar (some sharing 100% aa identity) to that of E. coli 1.1.43, an isolate from a human gastrointestinal tract. In contrast, while the soil sample contained the gull variant, it also contained sequence diversity that did not match any known clinical isolates. Hence, gull AR gene diversity does not appear to simply reflect the diversity found in soils (and therefore, perhaps, the broader environment), although further work is needed to confirm this hypothesis.

Class A β-lactamases were also common in our samples. In a recent study of AR in Alaskan soil, class B β-lactamases were most common (Allen et al., 2009). We did not detect any class B types from our samples, however, indicating that the relative abundance of β-lactamase classes may vary by environment or location.

Only two of the ARDB β-lactamase gene types that we identified have been reported previously in gulls (Table 2). Notably, one of these genes was classified as a CTX-M-like ESBL. ESBL-producing organisms are a major public health concern in clinics and communities (Pitout and Laupland, 2008). However, the variant was also 100% similar to that previously found in R. aquatilis (Enterobacteriaceae), and the flanking sequences also suggest a Rahnella host. Rahnella has been implicated in several instances of infectious disease in humans, causing bacteremia (Chang et al., 1999; Tash, 2005). R. aquatilis has also been found in the guts of insects (e.g., Morales-Jimenez et al., 2009) and a wild fish (Skrodenyte-Arbaciauskiene et al., 2008); however, as far as we know, this is the first report of the genus in a wild bird.

Although we generally detected few tetracycline resistance genes in our samples, we identified five known tetracycline resistance gene types in gulls and a sixth type in soil. tetL and tetM have been reported before in a few studies of gulls and other wildlife (Table 1). Notably we did not detect tetA and tetB, which have
been widely reported in other wildlife (e.g., Silva et al., 2010; Alroy and Ellis, 2011). The gene tetW has only been reported in one study of wild animals (Jeters et al., 2009). tetC has also been reported in one other study of wildlife; the gene was found in small rodents trapped at swine farms, suggesting that the presence of the gene may have resulted from agricultural use of antibiotics. Interestingly, several other studies were unable to detect tetC in wildlife using PCR (e.g., Rybarikova et al., 2010; Ahmad et al., 2011). One other study of wild animals detected tetO in housefies and German cockroaches at swine farms (Ahmad et al., 2011). Thus, gulls from Appledore Island may have acquired some tet genes from agricultural sources.

In addition to these well-known AR genes, both gulls and soil also harbor a variety of previously unknown AR genes. Given that the genes confer resistance in *E. coli*, they clearly have the potential to be functional in human pathogens. Some of these genes may have originally derived from human bacteria and have yet to be detected in clinical settings. Indeed, Sommer et al. (2009) detected a variety of novel AR genes in healthy humans using the same method. Alternatively, the genes may be intrinsic to the birds’ commensal flora or more broadly, to the environment. In this case, the mixing of human and gull fecal bacteria could result in novel combinations and mechanisms of AR in human beings.

In conclusion, by using a functional metagenomics approach, this study more than doubled the number of clinically relevant AR gene types known to be carried by gulls or by wildlife in general. Together with the propensity of gulls to visit human-dominated habitats, this high diversity of AR gene types suggests that gulls can facilitate the spread of AR. Further, the large number of novel genes that we identified suggests that gulls also have the potential to introduce new mechanisms of AR back to the human microflora.

**ACKNOWLEDGMENTS**

We would like to thank the staff of the Shoals Marine Laboratory for sampling assistance, George Jacoby for helpful comments on the manuscript, the University of California, Irvine (to Jennifer B. H. Martiny), and Tufts Cummings School of Veterinary Medicine (to Julie C. Ellis) for supporting the work.
