Abstract—In this paper we construct a deterministic polynomial time algorithm for the problem where a set of users is interested in gaining access to a common file, but where each has only partial knowledge of the file. We further assume the existence of another set of terminals in the system, called helpers, who are not interested in the common file, but who are willing to help the users. Given that the collective information of all the terminals is sufficient to allow recovery of the entire file, the goal is to minimize the (weighted) sum of bits that these terminals need to exchange over a noiseless public channel in order achieve this goal. Based on established connections to the multi-terminal secrecy problem, our algorithm also implies a polynomial-time method for constructing the largest shared secret key in the presence of an eavesdropper. We consider the following side-information settings: (i) side-information in the form of uncoded packets of the file, where the terminals’ side-information consists of subsets of the file; (ii) side-information in the form of linearly correlated packets, where the terminals have access to linear combinations of the file packets; and (iii) the general setting where the the terminals’ side-information has an arbitrary (i.i.d.) correlation structure. We provide a polynomial-time algorithm (in the number of terminals) that finds the optimal rate allocations for these terminals, and then determines an explicit optimal transmission scheme for cases (i) and (ii).

I. INTRODUCTION

In recent years cellular systems have witnessed significant improvements in terms of data rates, and are nearly approaching the theoretical limits in terms of the physical layer spectral efficiency. At the same time, the rapid growth in the popularity of data-enabled mobile devices, such as smart phones and tablets, and the resulting explosion in demand for more throughput are challenging our abilities even with the current highly efficient cellular systems. One of the major bottlenecks in scaling the throughput with the increasing number of mobile devices is the “last mile” wireless link between the base station and the mobile devices – a resource that is shared among many terminals served within the cell. This motivates the study of paradigms where cell phone devices can cooperate among themselves to get the desired data in a peer-to-peer fashion without solely relying on the base station.

An example of such a setting is shown in Figure 1, where a base station wants to deliver the same file to multiple geographically-close users over an unreliable wireless downlink. We assume that some terminals, which are in the range of the base station, are not interested in the file, but due to their proximity to the base station, they are able to overhear some of its transmissions. Moreover, we assume that these terminals are willing to help in distributing the file to the respective users. We will refer to these terminals as helpers. In the example of Figure 1, we assume that the file consists of four equally sized packets \( w_1, w_2, w_3, w_4 \) belonging to some finite field \( \mathbb{F}_q \). Suppose that after a few initial transmission attempts by the base station, the three terminals (including one helper) individually receive only parts of the file (see Figure 1), but collectively have the entire file. Now, if all terminals are in close vicinity and can communicate with each other, then, it is much more desirable and efficient, in terms of resource usage, to reconcile the file among users by letting all terminals “talk” to each other without involving the base station. The cooperation among the terminals has the following advantages:

* Local communication among terminals has a smaller footprint in terms of interference, thus allowing one to use the shared resources (code, time or frequency) freely without penalizing the base station’s resources, i.e., higher resource reuse factor.
* Transmissions within the close group of terminals is much more reliable than from the base station to any...
terminal due to geographical proximity of terminals.

- This cooperation allows for the file recovery even when
  the connection to the base station is either unavailable
after the initial phase of transmission, or it is too weak
to meet the delay requirement.

The problem of reconciling a file among multiple wireless
users having parts of it while minimizing the cost in terms of
the total number of bits exchanged is known in the literature
as the data exchange problem and was introduced by El
Rouayheb et al. in [1]. In the problem formulation of the data
exchange problem it is assumed that all the terminals in the
system are interested in recovering the entire file, i.e., there
are no helpers. For data exchange problem without helpers
a randomized algorithm was proposed in [2] and [3], while a
deterministic polynomial time algorithms was proposed in [4],
[5].

In this paper we consider a scenario with helpers, and linear
communication cost. W.r.t. the example considered here, if
user 1, user 2 and the helper transmit $R_1$, $R_2$ and $R_3$ bits,
respectively, the data exchange problem with helpers would
correspond to minimizing the weighted sum-rate $\alpha_1 R_1 +
\alpha_2 R_2 + \alpha_3 R_3$ such that, when the communication is over,
user 1 and user 2 can recover the entire file. It can be shown
that for the case when $\alpha_1 = \alpha_2 = \alpha_3 = 1$, the minimum
communication cost is 2 and can be achieved by the following
coding scheme: user 2 transmits packet $w_4$, and the helper
transmits $w_1 + w_3$, where the addition is over the underlying
field $\mathbb{F}_q$. This corresponds to the optimal rate allocation
$R_2 = R_3 = 1$ symbol in $\mathbb{F}_q$. If there was no helper in the
system, it would take a total of 3 transmissions to reconcile the
file among the two users. That is user 1 has to transmit $w_3$ and
user 2 transmits $w_1$ and $w_4$. Thus, the helpers can contribute
to lowering the total communication cost in the system.

The discussion above considers only a simple form of side-
information, where different terminals observe partial uncoded
“raw” packets of the original file. Content distribution net-
works are increasingly using coding, such as Fountain codes
or linear network codes, to improve the system efficiency [6].
In such scenarios, the side-information representing the partial
knowledge gained by the terminals would be coded and in
the form of linear combinations of the original file packets,
rather than the raw packets themselves. The previous two
cases of side-information (“raw” and coded) can be regarded
as special cases of the more general problem where the side-
information has arbitrary correlation among the data observed
by the different terminals and where the goal is to minimize
the weighted total communication cost. In [7] Csiszár
and Narayan posed a related security problem referred to as
the “multi-terminal key agreement” problem. They showed that
obtaining the file among the users in minimum number of bits
exchanged over the public channel is sufficient to maximize
the size of the secret key shared between the users. This
result establishes a connection between the Multi-party key
agreement and the Data exchange problem with helpers. [7]
solves the key agreement problem by formulating it as a linear
program (LP) with an exponential number of rate-constraints,
corresponding to all possible cut-sets that need to be satisfied.

In this paper, we make the following contributions. First,
we provide a deterministic polynomial time algorithm for
finding an optimal rate allocation, w.r.t. a weighted sum-rate
cost needed to deliver the file to all users when all
 terminals have arbitrarily correlated side-information. For the
data exchange problem with helpers, this algorithm computes
the optimal rate allocation in polynomial time for the case of
linearly coded side-information (including the “raw” packets
 case) and for the general linear cost functions (including the
sum-rate case). Second, for the the data exchange problem
with helpers, with raw or linearly coded side-information, we
propose an efficient communication scheme design based on
the algebraic network coding framework [8], [9].

II. SYSTEM MODEL AND PRELIMINARIES

In this paper, we consider a set up with $m$ terminals out of
which some subset of them is interested in gaining access to
a file or a random process. Let $X_1, X_2, \ldots, X_m$, $m \geq 2$,
denote the components of a discrete memoryless multiple
source (DMMS) with a given joint probability mass function.
Each user $i \in M \triangleq \{1, 2, \ldots, m\}$ observes $n$ i.i.d. realizations
of the corresponding random variable $X_i$.

Let $\mathcal{A} = \{1, 2, \ldots, k\} \subseteq M$ be the subset of terminals,
called users, who are interested in gaining access to the file,
\textit{i.e.}, learning the joint process $X_M = (X_1, \ldots, X_m)$. The
remaining terminals $\{k+1, \ldots, m\}$ serve as helpers, \textit{i.e.}, they
are not interested in recovering the file, but they are willing
to help users in the set $\mathcal{A}$ to obtain it. In [7], Csiszár
and Narayan showed that deliver the file to all users in a setup
with general DMMS interactive communication is not needed.
As a result, in the sequel WLOG we can assume that the
transmission of each user is only a function of its own initial
observations. Let $F_i \triangleq f_i(X^n_i)$ represent the transmission of
the user $i \in M$, where $f_i(\cdot)$ is any desired mapping of the
observations $X^n_i$. For each user in $\mathcal{A}$ in order to recover the
entire file, transmissions $F_i$, $i \in M$, should satisfy,

$$\lim_{n \to \infty} \frac{1}{n} H(X^n_M | F, X^n_t) = 0, \ \forall t \in \mathcal{A}, \quad (1)$$

where $X_M = (X_1, X_2, \ldots, X_m)$.

**Definition 1.** A rate tuple $R = (R_1, R_2, \ldots, R_m)$ is an
achievable data exchange (DE) rate tuple if there exists a
communication scheme with transmitted messages $F =
(F_1, F_2, \ldots, F_m)$ that satisfies (1), and is such that

$$R_i = \lim_{n \to \infty} \frac{1}{n} H(F_i), \ \forall i \in M. \quad (2)$$

It is easy to show using cut-set bounds that all the achievable
DE rate tuple’s necessarily belong to the following region

$$R \triangleq \{ R : R(S) \geq H(X_S | X_{S^c}), \ \forall S \subset M, \ A \not\subseteq S \}, \quad (3)$$

where $R(S) = \sum_{i \in S} R_i$. Also, using a random coding
argument, it can be shown that the rate region $R$ is an
achievable rate region [7].
In this work, we aim to design a polynomial complexity algorithm that delivers the file to all users in \( A \) while simultaneously minimizing a linear communication cost function \( \sum_{i=1}^{m} \alpha_i R_i \), where \( \alpha \triangleq (\alpha_1, \cdots, \alpha_m) \), \( 0 \leq \alpha_i < \infty \), is an \( m \)-dimensional vector of non-negative finite weights. We allow \( \alpha_i \)’s to be arbitrary non-negative constants, to account for the case when communication of some group of terminals is more expensive compared to the others, e.g., setting \( \alpha_1 \) to be a large value compared to the other weights minimizes the rate allocated to the user 1. This goal can be formulated as the following linear program:

\[
\begin{align*}
\min_{\mathbf{R}} & \quad \sum_{i=1}^{m} \alpha_i R_i, \\
\text{s.t.} & \quad R(S) \geq H(X_S|X_{S'}, X_1), \forall S \subset M, A \not\subseteq S.
\end{align*}
\]

### A. Finite Linear Source Model

In general an efficient content distribution networks use coding such as fountain codes or linear network codes. This results in terminals’ observations to be in the form of linear codes such as fountain codes or linear network codes. This is known in literature as Wolf problem \([12]\) for which the achievable rate region has the following form:

\[
\begin{align*}
\min_{\mathbf{R}} & \quad \sum_{i=1}^{m} \alpha_i R_i, \\
\text{s.t.} & \quad R(S) \geq H(X_S|X_{S'}, X_1), \forall S \subseteq M \setminus \{1\}.
\end{align*}
\]

Optimization problem (7) can be solved analytically due to the fact that the set function 

\[ f(S) = H(X_S|X_{S'}, X_1), \forall S \subseteq M \setminus \{1\} \]

is supermodular (see [13] for the formal definition). Therefore, optimization problem (7) is over a supermodular polyhedron \( \mathcal{R}_1 \). From the combinatorial optimization theory it is known that Edmonds’ greedy algorithm \([14]\) renders an analytical solution to this problem (see Algorithm 1).

**Algorithm 1** Edmonds’ algorithm applied to our problem

1. Set \( j_1, j_2, \ldots, j_{m-1} \) to be an ordering of \( \{1, 2, \ldots, m\} \setminus \{1\} \) such that \( \alpha_{j_1} \leq \alpha_{j_2} \leq \cdots \leq \alpha_{j_{m-1}} \).
2. for \( i = 1 \) to \( m - 1 \) do
3. \( R_i^* = H(X_{j_i}|X_{j_1}, X_{j_2}, \ldots, X_{j_{i-1}}) \).
4. end for

**Example 1.** Consider a system with \( m = 6 \) terminals \( M = \{1, 2, 3, 4, 5, 6\} \). For convenience, we express the underlying data vector as \( \mathbf{W} = [a \ b \ c]^T \in \mathbb{F}_q^3 \), where \( a, b, c \) are independent uniform random variables in \( \mathbb{F}_q \). Let us consider the case where each node has the following observations:

- \( X_1 = \{a+b\} \), \( X_2 = \{a+c\} \), \( X_3 = \{b+c\} \), \( X_4 = \{a\} \), \( X_5 = \{b\} \), \( X_6 = \{c\} \).

Let us assume that user 1 is interested in recovering the vector \( \mathbf{W} \) such that underlying communication cost is \( \sum_{i=2}^{6} R_i \).

It immediately follows from Algorithm 1 that a solution to this problem is \( R_2^* = R_3^* = 1 \), and \( R_4^* = R_5^* = R_6^* = 0 \). In other words, user 1 is missing 2 linear equations in order to be able to decode all 3 data packets.

### B. Deterministic Algorithm when \( |A| > 1 \)

In this section we extend the results from the previous section to the case where the set \( A \) contains arbitrary number of users. Optimization problem (4) can be written as follows:

\[
\begin{align*}
\min_{\mathbf{Z}, \mathbf{R}} & \quad \sum_{i=1}^{m} \alpha_i Z_i, \\
\text{s.t.} & \quad Z_i \geq R_i^{(l)}, \forall l \in A, \forall i \in M \setminus \{l\}, \\
& \quad \mathbf{R}^{(l)} \in \mathcal{R}_l, \forall l \in A,
\end{align*}
\]

where

\[ \mathcal{R}_l = \{\mathbf{R} : R(S) \geq H(X_S|X_{S'}, X_1), \forall S \subseteq M \setminus \{l\}\} .\]

Equivalence between the optimization problems (4) and (9) follows from the fact that transmissions of all terminals in \( M \) have to be such that all users in \( A \) can learn \( \mathbf{X}_M \). Optimization problem (9) has an exponential number constraints, which makes it challenging to solve in polynomial time. To obtain a
onto the hyperplane

\begin{equation}
\max_{\Lambda} \sum_{i=1}^{k} g^{(i)}(\Lambda^{(i)}),
\end{equation}

\begin{equation}
\text{s.t. } \sum_{i=1}^{k} \lambda^{(i)}_{l} = \alpha_{l}, \lambda^{(i)}_{l} \geq 0, \forall l \in \mathcal{A}, \forall i \in \mathcal{M} \setminus \{l\},
\end{equation}

where

\begin{equation}
g^{(i)}(\Lambda^{(i)}) = \min_{R^{(i)}} \sum_{l \in \mathcal{M} \setminus \{l\}} \lambda^{(i)}_{l} R^{(i)}_{l}, \text{ s.t. } R^{(i)} \in \mathcal{R}_{i}.
\end{equation}

Dual variable $\Lambda$ in the above problem is represented in matrix form as follows.

\begin{equation}
\Lambda = \begin{bmatrix}
\lambda^{(1)}_{1} & \lambda^{(1)}_{2} & \cdots & \lambda^{(1)}_{m} \\
\lambda^{(2)}_{1} & \lambda^{(2)}_{2} & \cdots & \lambda^{(2)}_{m} \\
\vdots & \vdots & \ddots & \vdots \\
\lambda^{(k)}_{1} & \lambda^{(k)}_{2} & \cdots & \lambda^{(k)}_{m}
\end{bmatrix}.
\end{equation}

We denote by $\Lambda_{i}$ and $\Lambda^{(i)}$, the $i^{th}$ column vector and $l^{th}$ row vector of the matrix $\Lambda$, respectively. Moreover, we denote by $R^{(i)}$

\begin{equation}
\tilde{R} = \begin{bmatrix}
R^{(1)}_{1} & R^{(1)}_{2} & \cdots & R^{(1)}_{n} \\
R^{(2)}_{1} & R^{(2)}_{2} & \cdots & R^{(2)}_{n} \\
\vdots & \vdots & \ddots & \vdots \\
R^{(k)}_{1} & R^{(k)}_{2} & \cdots & R^{(k)}_{n}
\end{bmatrix}
\end{equation}

the rate matrix whose $l^{th}$ row, here denoted by $\tilde{R}(l)$, represents an optimizer of the problem (11) w.r.t. the weight vector $\Lambda^{(i)}$. In order to ensure consistency with the optimization problem (10) observe that $\lambda^{(i)}_{l} = 0$, and $R^{(i)}_{l} = 0, \forall l = 1, \ldots, k$.

For any given user $l \in \mathcal{A}$, the objective function (11) of the dual problem (10) can be computed analytically using Algorithm 1. The optimization problem (10) is a linear program (LP) with $O(n \cdot k)$ number of constraints, which makes it possible to solve it in polynomial time (w.r.t. number of terminals). To solve the optimization problem (10) we apply a subgradient method, as described below.

Starting with a feasible iterate $\Lambda[0]$ w.r.t. the optimization problem (10), every subsequent iterate $\Lambda[n]$ can be recursively represented as an Euclidean projection of the vector

\begin{equation}
\Lambda_{i}[n] = \Lambda_{i}[n - 1] + \theta[n - 1] \cdot \tilde{R}_{i}[n - 1], \forall i \in \mathcal{M}
\end{equation}

onto the hyperplane \( \{ \Lambda_{i} \geq \alpha_{i} \} \), where \( \tilde{R}_{i}[n - 1] \) is the $i^{th}$ column of the rate matrix $\tilde{R}[n - 1]$. The Euclidean projection ensures that every iterate $\Lambda[n]$ is feasible w.r.t. the optimization problem (10). It is not hard to verify that the following initial choice of $\Lambda[0]$ is feasible w.r.t. the problem (10).

\begin{equation}
\lambda^{(i)}[0] = \begin{cases}
\frac{\alpha_{i}}{k} & \text{if } i \not\in \mathcal{A} \\
\frac{\alpha_{i}}{\sum_{i=1}^{k} \alpha_{i}} & \text{if } i \in \mathcal{A} \setminus \{l\}, \forall i \in \mathcal{M}, \forall l \in \mathcal{A}.
\end{cases}
\end{equation}

By appropriately choosing the step size $\theta[n]$ in each iteration (14), it is guaranteed that the subgradient method described above converges to the optimal solution of the problem (10). To recover the primal optimal solution from the iterates $\Lambda[n]$ we use results from [15], where at each iteration of (14), the primal iterate is constructed as follows.

\begin{equation}
\tilde{R}[n] = \sum_{j=1}^{n} \mu^{(n)}_{j} \tilde{R}[j],
\end{equation}

where

\begin{equation}
\sum_{j=1}^{n} \mu^{(n)}_{j} = 1, \mu^{(n)}_{j} \geq 0, \text{ for } j = 1, 2, \ldots, n.
\end{equation}

By carefully choosing the step size $\theta[n]$, $\forall n$ in (14) and the convex combination coefficients $\mu^{(n)}_{j}$, $\forall j = 1, \ldots, n$, it is guaranteed that (16) converges to the minimizer of (2), and therefore to the minimizer of the original problem (3). In [15], the authors proposed several choices for $\{\theta[n]\}$ and $\{\mu^{(n)}_{j}\}$ which lead to the primal recovery. Here we list some of them.

1) $\theta[n] = \frac{a}{b + cn}$, $\forall n$, where $a > 0, b \geq 0, c > 0$, $\mu^{(n)}_{j} = \frac{1}{n}$, $\forall j = 1, \ldots, n$, $\forall n$.
2) $\theta[n] = n^{-a}$, $\forall n$, where $0 < a < 1$, $\mu^{(n)}_{j} = \frac{1}{n}$, $\forall j = 1, \ldots, n$, $\forall n$.

Now, it is only left to compute an optimal rate allocation w.r.t. to the problem defined in (4). Let $R^{*}$ and $Z^{*}$ be the optimal rate vectors of the problems (4) and (9), respectively. As we pointed out earlier $R^{*} = Z^{*}$, where $Z^{*}$ can be computed from the matrix $\tilde{R}[n]$ for a sufficiently large $n$, as follows.

\begin{equation}
Z^{*} = \max \left\{ \tilde{R}^{(1)}[n], \tilde{R}^{(2)}[n], \ldots, \tilde{R}^{(k)}[n] \right\}, \forall i \in \mathcal{M}.
\end{equation}

Pseudo code of the algorithm described in this section is shown below (see Algorithm 2).

\textbf{Algorithm 2 Optimal DE rate allocation}

1: Initialize $\Lambda[0]$ according to (15)
2: Set $\theta[n] = \frac{1}{n+1}$, $\forall n$, $\mu^{(n)}_{j} = \frac{1}{n}$, $\forall j = 1, \ldots, n$.
3: for $n = 1$ to $\tilde{n}$ do
4: for $l = 1$ to $k$ do
5: Compute $\tilde{R}^{(l)}[n]$ using Algorithm 1 for the weight vector $\Lambda^{(l)}[n]$.
6: end for
7: Project $\Lambda_{i}[n] = \Lambda_{i}[n - 1] + \theta[n - 1] \cdot \tilde{R}_{i}[n - 1]$ onto the hyperplane $\{ \Lambda_{i} \geq \alpha_{i} \}$.
8: end for
9: $\tilde{R}[n] = \sum_{j=1}^{n} \mu^{(n)}_{j} \tilde{R}[j]$
10: $R^{*} = \max \left\{ \tilde{R}^{(1)}[n], \tilde{R}^{(2)}[n], \ldots, \tilde{R}^{(k)}[n] \right\}$

C. Code Construction for the Linear Source Model

In this Section we briefly address the question of the optimal code construction for the linear source model. For that matter, let us consider the following example.
Example 2. Let us consider the same source model as in Example 1, where \( A = \{1, 2, 3\} \), and the objective function is \( \sum_{i=1}^{\infty} R_i \). Applying the algorithm described above, we obtain
\[
R_1^* = R_2^* = R_3^* = \frac{1}{4}, \quad R_4^* = R_5^* = R_6^* = \frac{1}{2}.
\]
(19)

This solution suggests that in order to design a scheme that performs optimally, it is necessary to split all the packets into 4 equally sized chunks. In other words, terminals’ observations can be written as \( X_1 = a + b = \{a_1 + b_1, a_2 + b_2, a_3 + b_3, a_4 + b_4\} \), \( X_2 = a + c = \{a_1 + c_1, a_2 + c_2, a_3 + c_3, a_4 + c_4\} \), etc., where all \( a_i \)'s, \( b_i \)'s and \( c_i \)'s belong to \( \mathbb{F}_q/\mathbb{F}_2 \). For this extended source model we have that the optimal rate allocation is \( R_1^* = R_2^* = R_3^* = 1, \quad R_4^* = R_5^* = R_6^* = 2 \).

Next question we need to address is how to design transmissions of each user? Starting from an optimal (integer) rate allocation, we first construct the corresponding multicast network (see Figure 2). In this construction, notice that there are several types of nodes. First, there is a super node \( S \) that possesses all the packets. Each user in the set \( A \) plays the role of a transmitter and a receiver, while the helpers act only as transmitters. To model this, we denote \( s_1, \ldots, s_6 \) to be the “sending” nodes, and \( r_1, r_2 \) and \( r_3 \) to be the receiving nodes. To model the side-information at users 1, 2 and 3, we introduce links \( (s_i, r_j) \), \( i = 1, 2, 3 \), of capacity 4, which are routing the users’ observations to the corresponding receiving nodes. To model the broadcast nature of each transmission, we introduce “dummy” nodes \( t_1, \ldots, t_6 \), such that the capacity of the links \( (s_i, t_j) \) is the same as link capacity \( (t_i, r_j) \), \( j \neq i \), and is equal to \( R_i^* \), \( \forall i \in M \).

To solve for actual transmissions of each terminal, we apply the algebraic network coding approach [8], with appropriately designed source matrix \( A \) which corresponds to the side-information of all terminals. Finally, the network code for the data exchange problem with helpers can be constructed in polynomial time from the algorithms provided in [9] which are based on a simultaneous transfer matrix completion.

IV. CONCLUSION AND EXTENSIONS

In this paper we study the data exchange problem with helpers. We provide a deterministic polynomial time algorithm for minimizing the weighted sum-rate cost of communication. We show that the data exchange problem with only one user and many helpers can be solved analytically using Edmonds’ algorithm. Further using single user solution as a building block we show how one can solve the more general problem with arbitrary number of users. Several extensions are of interest. For instance, we can consider a modification of the original data exchange problem where only helpers are allowed to transmit. Starting from a single user case, it is easy to see that an achievable rate tuple must satisfy all the cut-set constraints over the helper set such that the user is always on the receiving side of the cut. Minimizing the weighted sum-rate cost over all achievable rate tuples can again be done using Edmonds’ algorithm (see Algorithm 1). Finally, extension to the multiple user case corresponds to the weighted sum-rate minimization over all rate tuples that are simultaneously achievable for all users. This optimization problem can be solved in polynomial time using the same approach as in Algorithm 2.
