Abstract
We present high order surface finite element methods for the linear analysis of seven-parameter shells. The special feature of these methods is that they work with the exact geometry of the shell reference surface which can be given parametrically by a global map or implicitly as the zero level-set of a level set function. Furthermore, a special treatment of singular parametrizations is proposed. For the approximation of the shell displacement parameters we have implemented arbitrary order hierarchical shape functions on quadrilateral and triangular meshes. The methods are verified by a convergence analysis in numerical experiments.

Keywords Shells · Surface finite elements · Exact geometry · Implicit geometry · Higher order

1 Introduction
Due to their efficient load-carrying capabilities, shell structures enjoy widespread use in a variety of engineering applications. Therefore, a huge amount of research work has been devoted to the development of shell models (e.g. [11,15]), their formal justification (e.g. [12–14]), as well as to the realization of numerical methods (e.g. [8,9]). It is well known that shell structures are sensitive to geometric imperfections [30]. Even worse, the approximation of the geometry leads to wrong solutions in some situations, see the plate paradox investigated e.g. in [2]. Furthermore, e.g., in contact problems an exact description of smooth geometries is of interest. Among others, these examples motivated us to develop shell finite element methods based on the exact geometry. Therefore, the literature review concentrates on geometry representation.

Usually, the exact geometry is approximated. In the simplest case, planar facet elements are deployed. However, those elements can only poorly represent curved structures and are not reliable due to a missing bending–stretching coupling on the element level. In order to represent the geometry more accurately high order (often quadratic) shape functions are used. To our best knowledge, exact geometry methods for shell analysis are restricted to the case where the exact geometry is parametrically defined. A finite element method which allows for arbitrary parametrizations is described in [1]. Therein, the field approximation based on Lagrange elements is applied to a seven-parameter shell theory considering geometrical nonlinearities and functionally graded shells. However, the actual computation of the arising integrals is carried out by symbolic algebra subroutines written in MAPLE. In [31], an exact geometry method based on the blending function method is presented. Furthermore, in the work [29] a finite element method for geometrically nonlinear problems is developed. Therein, the exact geometry of the shell is captured by an initial deformation of a flat reference configuration. However, since most CAD systems use NURBS functions, it is reasonable to restrict the input parametrizations for the shell analysis to NURBS [10]. This has the advantage that the parametrization is given as a product of basis functions and coefficients. Thus, derivatives are easily computed if the derivatives of the basis functions are known. Following the concept of Isogeometric Analysis, shell finite elements based on different shell models were proposed in [5,23,24,28] among others. Therein, the reference surface is described by NURBS, just as the field approximation.

Shell problems can also be seen as one application of the more general concept of partial differential equations defined on surfaces. We mention [17] for an overview of related finite element methods. To our best knowledge the first exact geometry method for the Laplace–Beltrami operator on implicitly defined surfaces was presented in [16]. Therein, the exact geometry of closed smooth surfaces is parametrized over a space triangulation by means of the closest point projection. Recently, a directional mapping based on predefined search directions was considered to construct high order geometry approximations [20, 25]. In [22], the search direction has been tailored such that the exact geometry of smooth surfaces with boundaries is available in the finite element analysis.

In the present paper we consider shells with parametrically and implicitly defined reference surfaces. For both cases exact geometry finite element methods are presented. For implicitly defined shells the reference surface is parametrized over a space triangulation following the developments presented in [22]. Thus, the implicit setting is reformulated to the parametrized setting. The curvature of the reference surface is necessary within the considered variational formulation, and so are the second order partial derivatives of the parametrization. In the case of a parametrically defined surface they are obtained by automatic differentiation based on hyper-dual numbers [19]. For the case of an implicitly defined surface, we derive a formula such that only the second order derivatives of the level-set function \( \phi \) are needed. As a shell model we use a displacement based seven-parameter model accounting for stretching, bending, shear deformations, and through-the-thickness stretching (see [1, 7, 15]). We restrict ourselves to a linear elastic analysis, i.e. small distortions, and through-the-thickness stretching (see [1, 7, 15]). We remark that the differential geometry in the context of thin-walled structures is exhaustively discussed in [3] and [11], among others.

The underlying assumption in shell analysis is that the computational domain \( \Omega \subset \mathbb{R}^3 \) has a small extension in one coordinate compared to the two others. Thus, we assume that \( \Omega \) is located around a two-dimensional reference surface \( \bar{\Omega} \).

### 2 Differential geometry and shell model

In this section, we recall the differential geometry of thin-walled structures and introduce the displacement based seven-parameter shell model. First, the geometry of the reference surface is presented. Then, the reference surface is extended to the three-dimensional shell volume, for which we present the geometric relations. In a next step, the three-dimensional shell problem is introduced. Finally, the kinematics are restricted to a seven-parameter shell model.

We remark that the differential geometry in the context of thin-walled structures is exhaustively discussed in [3] and [11], among others.

The underlying assumption in shell analysis is that the computational domain \( \Omega \subset \mathbb{R}^3 \) has a small extension in one coordinate compared to the two others. Thus, we assume that \( \Omega \) is located around a two-dimensional reference surface \( \bar{\Omega} \).

#### 2.1 Reference surface

In the present paper, we consider shell reference surfaces which are given parametrically or implicitly. In the former case we have a parametrization \( \bar{\mathbf{u}} : \bar{U} \subset \mathbb{R}^2 \rightarrow \bar{\Omega} \) available with given \( \bar{U} \). In the latter case, the reference surface is given as the zero-level set of a function \( \phi : \mathbb{R}^3 \rightarrow \mathbb{R} \) inside a cuboid \( B \)

\[
\bar{\Omega} = \{ \mathbf{x} \in B | \phi(\mathbf{x}) = 0 \}.
\]

For this setting, the normal vector to the surface is given by

\[
\bar{n}(\mathbf{x}) = \frac{\nabla \phi(\mathbf{x})}{||\nabla \phi(\mathbf{x})||}.
\]

In the numerical method, we will make use of a piecewise parametrization of the exact surface over a space triangulation. Therefore, the implicit description of the reference surface is turned into a parametric one. Thus, we consider the differential geometry of a parametrized surface in the rest of this section.

Given the parametrization \( \bar{\mathbf{u}} \), we can define the two covariant base vectors \( \bar{\mathbf{G}}_\alpha := \frac{\partial \bar{\mathbf{u}}}{\partial \alpha} \), which span the tangent plane to \( \bar{\Omega} \). Here and in the following, Greek indices take the values 1 and 2 and Latin indices the values 1, 2, 3. With the base vectors we can define the unit normal vector

\[
\bar{n} = \frac{\bar{\mathbf{G}}_1 \times \bar{\mathbf{G}}_2}{||\bar{\mathbf{G}}_1 \times \bar{\mathbf{G}}_2||}.
\]

and the covariant coefficients of the metric \( \bar{\mathbf{G}}_{\alpha\beta} = \bar{\mathbf{G}}_\alpha \cdot \bar{\mathbf{G}}_\beta \). The contravariant coefficients of the metric are given by

\[
\left[\bar{G}^{\alpha\beta}\right] = \left[\bar{G}_{\alpha\beta}\right]^{-1},
\]

where \( \left[\bar{G}_{\alpha\beta}\right] \) is the coefficient matrix. The contravariant base vectors can than be computed by \( \bar{G} = \bar{\mathbf{G}}^{-1} \).
$\bar{G}^{\alpha\beta} G_\beta$. Here, and in the following, the Einstein summation convention applies. Whenever an index occurs once in an upper position and in a lower position we sum over this index.

Due to the definition of the normal vector as a unit vector, we have $\mathbf{n} \cdot \mathbf{n} = 1$. Taking the derivative with respect to $\theta^\alpha$, yields $\frac{\partial}{\partial \theta^\alpha} (\mathbf{n} \cdot \mathbf{n}) = n_\alpha n + n \cdot n_\alpha = 0$. Thus, the derivatives of the normal vector are in the tangent plane of the surface. Expressing the derivatives of the normal vector through a linear combination of the tangent vectors yields

$$n_\alpha = -h^\alpha_\beta \bar{G}_\beta,$$

with

$$h_{\alpha\beta} = -\bar{G}_\alpha \cdot \mathbf{n}_\beta \quad \text{and} \quad h^\alpha_\beta = \bar{G}^{\beta\gamma} h_{\alpha\gamma}.$$

These relations are known as the Weingarten equations, first established in [34]. The functions $h_{\alpha\beta} = h_{\beta\alpha}$ are the coefficients of the second fundamental form. Furthermore, $H = \frac{1}{2} h^\gamma_\gamma$ is the mean curvature and $K = h^1_1 h^2_2 - h^1_2 h^2_1$ is the Gaussian curvature of the surface.

### 2.2 Geometry of the shell volume

In this section, we assume that we have a parametrization $\bar{\mathbf{g}}$ of the reference surface $\bar{\varnothing}$ available. Then the parametrization of the shell volume $\varnothing$ is given by

$$\mathbf{g} : (\bar{\varnothing} \times T) \subset \mathbb{R}^3 \rightarrow \varnothing \subset \mathbb{R}^3$$

$$(\theta^1, \theta^2) \times \theta^3 \mapsto \mathbf{g}(\theta^1, \theta^2, \theta^3) = \bar{\mathbf{g}}(\theta^1, \theta^2) + \theta^3 \mathbf{n},$$

with the interval $T = [-\tilde{t}/2, \tilde{t}/2]$, where $\tilde{t}$ is the thickness of the shell. The geometric setting is illustrated in Fig. 1. The first two base vectors in the shell volume are related to the base vectors at the reference surface by

$$G_\alpha = \mu^\beta_\alpha \bar{G}_\beta,$$

where $\mu^\beta_\alpha = (\delta^\beta_\alpha - \theta^3 h^\beta_\alpha)$ are the components of the shifter tensor and $\delta^\beta_\alpha$ is the Kronecker delta. Furthermore, $G_3 = \mathbf{n}$. Thus, the covariant components of the metric are given by

$$G_{\alpha\beta} = \mu^\gamma_\alpha \mu^\rho_\beta \bar{G}_{\gamma\rho} = \bar{G}_{\alpha\beta} - 2 (\theta^3) h_{\alpha\beta} + (\theta^3)^2 h_{\gamma\alpha} h^\gamma_\beta,$$

$$G_{\alpha3} = G_{3\alpha} = 0, \quad G_{33} = 1,$$

(8)

and the determinant of the metric is

$$d_G = \det((G_{ij})) = \left(1 - 2 (\theta^3) H + (\theta^3)^2 K \right)^2 \det((\bar{G}_{\alpha\beta})).$$

(9)

The components of the contravariant metric are

$$(G^{\alpha\beta}) = [G_{\alpha\beta}]^{-1}$$

$$= \frac{\text{adj}((\bar{G}_{\alpha\beta})) - 2 \theta^3 \text{adj}((h_{\alpha\beta})) + (\theta^3)^2 \text{adj}((h_{\gamma\alpha} h^\gamma_\beta))}{\det((\bar{G}_{\alpha\beta})) \left(1 - 2 H \theta^3 + K (\theta^3)^2 \right)^2}$$

$$G^{\alpha3} = G^{3\alpha} = 0, \quad G^{33} = 1,$$

(10)

where

$$\text{adj}((\bar{G}_{\alpha\beta})) = \begin{bmatrix} \bar{G}_{22} & -\bar{G}_{12} \\ -\bar{G}_{21} & \bar{G}_{11} \end{bmatrix}$$

(11)

is the adjugate matrix of $[\bar{G}_{\alpha\beta}]$.

### 2.3 The 3D shell problem

We continue with the statement of the three-dimensional shell problem, which is considered in the present paper to be a problem of linearized elasticity on shell-like domains $\varnothing$ with boundary $\Gamma$. The three-dimensional elasticity problem reads:

Find $\tilde{\mathbf{u}} : \varnothing \rightarrow \mathbb{R}^3$ such that
\[ \nabla \cdot \mathbf{\sigma} + \mathbf{b} = 0 \quad \text{in } \Omega, \]
\[ \mathbf{\sigma} = \tilde{C} : \mathbf{\epsilon} \quad \text{in } \Omega, \]
\[ \mathbf{\epsilon} = \frac{1}{2} \left( \nabla \tilde{\mathbf{u}} + (\nabla \tilde{\mathbf{u}}) \right)^\top \quad \text{in } \Omega, \]
\[ \tilde{\mathbf{u}} = \tilde{\mathbf{u}}_D \quad \text{on } \Gamma_D, \]
\[ \mathbf{t} = \mathbf{t}_N \quad \text{on } \Gamma_N. \] (12)

Here, \( \mathbf{\sigma} \) is the stress tensor, \( \mathbf{b} \) the bodyforce, \( \tilde{C} \) the elasticity tensor, \( \mathbf{\epsilon} \) the strain tensor, \( \tilde{\mathbf{u}}_D \) the given Dirichlet datum on \( \Gamma_D \), and \( \mathbf{t}_N \) the given Neumann datum on \( \Gamma_N \). We require that \( \Gamma = \Gamma_D \cup \Gamma_N \) and \( \Gamma_D \cap \Gamma_N = \emptyset \). Moreover, we assume that \( \Gamma_D \) is a subset of the lateral part of the boundary \( \Gamma \). We remark that all quantities with a tilde over them are defined on \( \Omega \) without reference to a specific parametrization. Furthermore, we have the following coordinate-free displacement-based variational formulation of (12): Find \( \tilde{\mathbf{u}} \in V \) such that

\[ \int_{\Omega} \tilde{\mathbf{e}}(\mathbf{\psi}) : \tilde{C} : \tilde{\mathbf{e}}(\tilde{\mathbf{u}}) \, d\mathbf{x} = \int_{\Omega} \mathbf{\psi} \cdot \mathbf{b} \, d\mathbf{x} + \int_{\Gamma_N} \mathbf{\psi} \cdot \mathbf{t}_N \, ds_N \quad \forall \mathbf{\psi} \in V_0, \] (13)

with \( V = \{ \tilde{\mathbf{u}} \in [H^1(\Omega)]^3 \mid \tilde{\mathbf{u}} = \tilde{\mathbf{u}}_D \text{ on } \Gamma_D \} \) and \( V_0 = \{ \mathbf{\psi} \in [H^1(\Omega)]^3 \mid \mathbf{\psi} = 0 \text{ on } \Gamma_D \} \).

In order to solve (13), we rewrite the problem in parametric coordinates. Instead of solving for \( \tilde{\mathbf{u}}(\mathbf{x}) \), \( \mathbf{x} \in \Omega \), we seek the displacement field \( \mathbf{u}(\theta^1, \theta^2, \theta^3) = \tilde{\mathbf{u}}(\mathbf{\theta}(\theta^1, \theta^2, \theta^3)) \) defined on the parametric space. This change of variables applies to all quantities analogously. In the present paper, we employ a linear isotropic material law, where the contravariant components of the elasticity tensor \( \tilde{C} = \tilde{C}^{ijkl} \mathbf{G}_i \otimes \mathbf{G}_j \otimes \mathbf{G}_k \otimes \mathbf{G}_l \) for a shell-like body are given by

\[ C^{\alpha \beta \gamma \rho} = \lambda G^{\gamma \rho} G^{\beta \gamma} + \mu \left( G^{\gamma \rho} G^{\beta \gamma} + G^{\beta \rho} G^{\gamma \beta} \right), \]
\[ C^{\alpha \beta 33} = C^{33 \alpha \beta} = \lambda G^{\alpha \beta}, \]
\[ C^{3333} = C^{33 \alpha 3} = C^{\alpha 333} = \mu G^{\alpha \beta}, \]
\[ C^{\alpha 3 \beta 3} = C^{3 \beta 3 \alpha} = C^{\alpha 3 \beta 3} = C^{\beta 3 \alpha 3} = \mu G^{\alpha \beta}, \]
\[ C^{\alpha 3 \beta \gamma} = C^{3 \beta \gamma \alpha} = C^{\alpha 3 \beta \gamma} = C^{\beta \gamma \alpha 3} = 0, \]
\[ C^{3333} = C^{33 \alpha 3} = C^{33 \alpha 3} = C^{\alpha 333} = 0, \]
\[ C^{3333} = \lambda + 2\mu. \] (14)

The Lamé constants are denoted with \( \lambda \) and \( \mu \).

### 2.4 Seven-parameter shell model

Up to this point, no approximation of the three-dimensional problem has been introduced. In this section, we introduce the seven-parameter shell model [1,7,15] by restricting the through-the-thickness kinematics of the shell to be of the form

\[ \mathbf{u}(\theta^1, \theta^2, \theta^3) = V_b(\theta^3) \tilde{u}_b(\theta^3, \theta^2) \mathbf{e}^i + V_t(\theta^3) \tilde{u}_t(\theta^1, \theta^2) \mathbf{e}^i + V_n(\theta^3) \tilde{u}(\theta^1, \theta^2) \mathbf{n}, \] (15)

where we made use of the following through-the-thickness functions

\[ V_b(\theta^3) = \frac{t - 2\theta^3}{2t}, \]
\[ V_t(\theta^3) = \frac{t + 2\theta^3}{2t}, \]
\[ V_n(\theta^3) = 1 - \frac{4(\theta^3)^2}{t^2}. \] (16)

In (15), we have introduced the seven parameters \( \tilde{u}_b(\theta^1, \theta^2), \tilde{u}_t(\theta^1, \theta^2), \) and \( \tilde{u}(\theta^1, \theta^2) \), which depend only on the position on the reference surface. While \( \tilde{u}_b(\theta^1, \theta^2) \) physically represent the Cartesian components of the displacement vector at the bottom surface (at \( \theta^3 = -t/2 \)), \( \tilde{u}_t(\theta^1, \theta^2) \) represent the Cartesian components of the displacement vector at the top surface (at \( \theta^3 = t/2 \)). The seventh parameter \( \tilde{u}(\theta^1, \theta^2) \) is included in order to circumvent Poisson thickness locking [6]. Inserting (15) into the kinematic relations for the linearized strain tensor \( \mathbf{\epsilon} = \epsilon_{ij} \mathbf{G}^i \otimes \mathbf{G}^j \) yields

\[ \epsilon_{\alpha \beta} = \frac{1}{2} J_3^i \left( \mu \alpha \beta \left( V_b u_{b, \beta} + V_t u_{t, \beta} \right) + \mu \beta \alpha \beta \left( V_b u_{b, \alpha} + V_t u_{t, \alpha} \right) - \mu \beta \alpha \beta V_n \right), \]
\[ \epsilon_{\alpha 3} = \epsilon_{3 \alpha} = \frac{1}{2} J_3^i \left( \mu \beta \alpha \beta \left( V_b u_{b, \alpha} + V_t u_{t, \alpha} \right) + \mu \beta \alpha \beta V_n \right), \] (17)
\[ \epsilon_{33} = \frac{1}{2} J_3^i \left( \mu \beta \alpha \beta \left( V_b u_{b, \alpha} + V_t u_{t, \alpha} \right) + \mu \beta \alpha \beta V_n \right), \]

with \( J_3^i = \mathbf{G}_i \cdot \mathbf{e}^i \). From the expression of \( \epsilon_{33} \) we see that the model can represent constant and linear normal strain states through the thickness.

### 3 Finite element method

In this section, we describe the developed finite element methods. The methods used for parametrically and implicitly defined shells differ from each other. However, in both cases, we employ the reference element technique for the construction of hierarchical \( H^1 \)-conforming shape functions of arbitrary degree [32]. These element shape functions are pieced together to FEM basis functions by establishing a
connection between local and global degrees of freedom. Furthermore, we use tensor-product (degenerated for triangles) Gauss–Legendre quadrature rules on the reference element for the integral evaluation. For shape functions of degree \( p \), \((p + 1)^2\) in-plane quadrature points are used on each element, whereas three quadrature points for the integration across the thickness are employed. In the following, \( \Phi^e \) denotes the local linear element mapping. The discretization of the seven parameters \( \{u_1, u_2, u_3\} \) of the parametric plane \( \bar{\Omega} \) is done by means of

\[
\{u_1, u_2, u_3\} \approx \{u_{1l}, u_{2l}, u_{3l}\} = \sum_{i=1}^{n_S} \{u_{1i}, u_{2i}, u_{3i}\} N_l(\theta^1, \theta^2),
\]

(18)

where \( \{u_{1l}, u_{2l}, u_{3l}\} \) are \( n_S \) unknown coefficients and \( N_l \) are the FEM basis functions.

3.1 FEM for shells defined by singular parametrizations

In this section, we describe the finite element method for the case where the parametrization \( \overline{\mathbf{g}} \) of the reference surface is explicitly available. The geometry mappings for this method are depicted in Fig. 2. We use a quadrilateralization of the parametric plane \( \bar{\Omega} \). In (13), the derivatives of \( \overline{\mathbf{g}} \) up to second order show up. In the present work we use an automatic differentiation schema based on an augmented algebra. To this end, a hyper-dual number class has been implemented providing operator overloading [19].

Special care has to be taken of singular parametrizations, where the determinant of the metric vanishes on some part of the geometry. In particular, we focus on the case where one side of the boundary is mapped to a single point in the real space. In this case, the stiffness matrix does not need to exist. We modify the ansatz space by combining and skipping basis functions. In the framework of Isogeometric Analysis, a similar strategy was considered in [33]. For presentational purposes, we assume that the boundary at the line \( \theta^1 = 0 \) in the parameter space is mapped to a single point \( P_0 \) in the real space,

\[
\overline{\mathbf{g}}(0, \theta^2) = P_0.
\]

(19)

Obviously,

\[
\overline{\mathbf{G}}_2 = 0 \quad \text{for } \theta^1 = 0,
\]

(20)

and the determinant of the metric is zero at the whole line \( \theta^1 = 0 \). We assume that apart from the line \( \theta^1 = 0 \) the parametrization is regular. Furthermore, it is assumed that \( \mathbf{G}_{11} > 0 \) and that the Laurent expansion of \( \sqrt[3]{\mathbf{G}_{11}} \) about \( \theta^1 = 0 \) is of the form

\[
\sqrt[3]{\mathbf{G}_{11}} = \frac{a_{-1}(\theta^2)}{\theta^1} + \sum_{i=0}^{\infty} (\theta^1)^i a_i(\theta^2).
\]

(21)

Investigation on the existence of

\[
\int_{\bar{\Omega}} \nabla v_h : \nabla v_h \, d\mathbf{x} = \int_{\bar{\Omega}} ((v_h, 1)^2 G^{11} + 2 v_h, 1 v_h, 2 G^{12} + (v_h, 2)^2 G^{22}) \sqrt[3]{\mathbf{G}_{11}} \, d\theta
\]

(22)

leads to the following modifications of the shape functions:

1. All vertex-based shape functions related to the vertices on \( \theta^1 = 0 \) are added up to one single shape function.
2. All edge-based shape functions related to the edges on \( \theta^1 = 0 \) are removed, i.e. the respective degrees of freedom are constrained to zero in the implementation.
3. No modification of the cell-based shape functions is made.

The problematic term is

\[
(v_h, 2)^2 G^{22} \sqrt[3]{\mathbf{G}_{11}} = (v_h, 2)^2 \frac{a_{-1}(\theta^2)}{\theta^1} + \text{higher order terms}.
\]

(23)
We remark that \( \psi_h \) are polynomials. The integral (22) exists if \( \psi_{h, 2} = 0 \) holds, i.e. \( \psi_h \) has to be constant with respect to \( \theta^2 \) or \( \psi_h = 0 \) on \( \theta^1 = 0 \). Writing

\[
\psi_{h, 2} = \sum_{i=0}^{p} \sum_{j=0}^{p} a_{ij} (\theta^1)^i (\theta^2)^j, \tag{24}
\]

the integral does not exist if any \( a_{ij} \neq 0 \). The non-vanishing functions on \( \theta^1 = 0 \) are related to the nodes and edges there. All cell-based shape functions vanish on the boundary. A function \( \psi_h \) which is constant with respect to \( \theta^2 \) can be constructed summing up all node-based functions. This gives one new shape function. The edge-based shape functions are of higher order with respect to \( \theta^2 \) on \( \theta^1 = 0 \), they are thus eliminated.

### 3.2 FEM for implicitly defined shells

In the case of an implicitly defined reference surface, the parametrization \( \bar{\Omega} \) over a flat parameter domain is not explicitly available. Therefore, the exact geometry is parametrized over a space triangulation \( T_h \). To this end, we follow the strategy developed in [22]. The geometric concept is illustrated for the example of a sphere in Fig. 3. As a starting point we assume that a triangulation in space \( T_h \) close to the exact surface is available. For each triangle \( \tau_e \in T_h \) we have the standard affine mapping \( \Phi_e \) which maps the reference triangle \( \tau_R \) to \( \tau_e \). We denote the piecewise flat surface defined by the triangulation by \( \bar{\Omega}_h \). In order to lift a point \( \mathbf{x} \in \bar{\Omega}_h \) to the exact surface we introduce the mapping \( a \) in the following implicit way

\[
a : \bar{\Omega}_h \rightarrow \bar{\Omega} \quad \mathbf{x} \mapsto a(\mathbf{x}) = \mathbf{x} + r(\mathbf{x}) \mathbf{s}(\mathbf{x}) \quad \text{such that} \quad \phi(a(\mathbf{x})) = 0. \tag{25}
\]

Here, \( \mathbf{s}(\mathbf{x}) \) are predefined search directions. The mapping \( a \) is implicitly defined because \( r(\mathbf{x}) \) is not explicitly known and has to be computed in each evaluation of \( a \) such that \( \phi(a(\mathbf{x})) = 0 \). We specify the search directions in (25) as follows. Let \( \mathcal{V} \) denote the set of all vertices of \( T_h \). We set

\[
\bar{s}_v(\mathbf{x}) = \frac{\nabla \phi(\mathbf{x})}{||\nabla \phi(\mathbf{x})||} \quad \text{for} \quad \mathbf{x} \in \mathcal{V}, \tag{26}
\]

where \( \nabla \phi \) is the usual gradient of the level-set function \( \phi \) in \( \mathbb{R}^3 \). To preserve the exact geometry, we apply a modification at the vertices on the boundary of \( B \). Thus, we set

\[
s_v(\mathbf{x}) = \begin{cases}
\bar{s}_v(\mathbf{x}) - (\bar{s}_v(\mathbf{x}) \cdot \mathbf{n}_{\partial B}(\mathbf{x})) \mathbf{n}_{\partial B}(\mathbf{x}) & \text{for} \quad \mathbf{x} \in \mathcal{V} \cap \partial B \\
\bar{s}_v(\mathbf{x}) & \text{else}
\end{cases}, \tag{27}
\]

where \( \mathbf{n}_{\partial B} \) are the normal vectors to \( \partial B \). Then the search direction field \( \mathbf{s}(\mathbf{x}) \) defined on \( \bar{\Omega}_h \) is obtained by linear interpolation of \( \mathbf{s}_v(\mathbf{x}) \). Thus, the search direction field \( \mathbf{s} \) is given as a linear finite element function. We remark that the mapping (25) requires the solution of a non-linear root finding problem, which is numerically realized with the Newton–Raphson method. We obtain an element-wise parametrization \( \varphi^e \) of \( \bar{\Omega} \) over the reference element \( \tau_R \) by
\[ \mathbf{g}^e : \mathbb{R}^2 \to \hat{\Omega} \quad \theta^1, \theta^2 \mapsto a(\Phi_e(\theta^1, \theta^2)) . \]  
\[ (28) \]

The evaluation of the integrals in (13) requires \( \mathbf{x} = \mathbf{g}^e(\theta^1, \theta^2) \), the base vectors \( \mathbf{G}_a \) and the coefficients of the second fundamental form \( h_{\alpha\beta} \). All other geometric quantities can be computed from them by algebraic operations. The formula
\[ \overline{\mathbf{G}}_a = \Phi^e_\alpha - \frac{\Phi^e_{,\alpha} \cdot \mathbf{n} + r \mathbf{s}_{,\alpha} \cdot \mathbf{n}}{\mathbf{s} \cdot \mathbf{n}} \mathbf{s} + r \mathbf{s}_{,\alpha} \]  
\[ (29) \]

for the computation of the base vectors can be found in [22].

Taking into account the dependencies
\[ \hat{\mathbf{n}}(\mathbf{x}) = \hat{\mathbf{n}}(\mathbf{g}^e(\theta^1, \theta^2)) = \mathbf{n}(\theta^1, \theta^2) \]  
\[ (30) \]

the chain rule results in
\[ \mathbf{n}, \beta = \nabla \hat{\mathbf{n}} \cdot \overline{\mathbf{G}}_\beta . \]  
\[ (31) \]

Together with (5) the coefficients of the second fundamental form can be computed by
\[ h_{\alpha\beta} = -\overline{\mathbf{G}}_\alpha \cdot (\nabla \hat{\mathbf{n}} \cdot \mathbf{G}_\beta) . \]  
\[ (32) \]

For the gradient of the normal vector we have
\[ \nabla \hat{\mathbf{n}} = \frac{\nabla \nabla \Phi}{||\nabla \Phi||} - \frac{\nabla \Phi \otimes \nabla \Phi}{||\nabla \Phi||^3} = \frac{\nabla \nabla \Phi - \hat{\mathbf{n}} \otimes \hat{\mathbf{n}}}{||\nabla \Phi||} . \]  
\[ (33) \]

Thus, we have to provide the second order derivatives of the level-set function \( \Phi \) in the implementation.

In order to clarify the explanations on the implicit method, we remark that the space triangulation represents an intermediate step in the method and does not define the geometry. The key ingredient of the implicit method is the mapping \( a \) defined in (25), which maps the space triangulation to the exact geometry. However, this mapping is only implicitly defined and a one dimensional root finding problem has to be solved for the evaluation. This is no problem because the integrals are approximated by quadrature. Thus, only a pointwise evaluation is necessary.

### 4 Numerical results

In this section, we demonstrate the correct implementation of the developed methods and their capabilities. The verification examples are based on the method of manufactured solutions in order to have exact solutions to compare with. As an error measure we use
\[ e_u = \sqrt{\sum_{\Omega} \int_{\Omega} \left( \left\{ (1) \right\}_{\Omega} \left( \left\{ (2) \right\}_{\Omega} - \left\{ (1) \right\}_{\Omega} \right) \right)^2 dx , \]  
\[ (34) \]

where \( \left\{ (1) \right\}_{\Omega}, \left\{ (2) \right\}_{\Omega} \) is the exact manufactured solution and \( \left\{ (1) \right\}_{\Omega}, \left\{ (2) \right\}_{\Omega} \) the numerical solution. In (34), the sum has to be understood over the seven shell model parameters.

#### 4.1 Verification example for a parametrically defined shell

In order to verify the implementation, we employ the method of manufactured solutions, which has been demonstrated in [21] for parametrically defined surfaces. In this example, we use the reference surface defined by the parametrization
\[ x = \frac{2 \theta^1 \theta^2 + 2 \theta^1 - \theta^2}{3} , \]  
\[ y = \frac{-\theta^1 \theta^2 + 2 \theta^1 + 2 \theta^2}{3} , \]  
\[ z = \frac{2 \theta^1 \theta^2 - \theta^1 + 2 \theta^2}{3} , \]  
\[ (35) \]

and \((\theta^1, \theta^2) \in [0, 0.56] \times [0, 0.65]\), see Fig. 4. The shell has the thickness \( t = 0.01 \). The Young’s modulus is \( E = 8 \cdot 10^4 \), whereas Poisson’s ration is \( v = 0.25 \). We study the convergence of the method under uniform mesh refinement. We remark that we have checked the convergence for different displacement fields. Here, we present the results for the prescribed solution \( \left\{ (1) \right\}_{\Omega} = \cos(20 \theta^1), \left\{ (1) \right\}_{\Omega} = 0, \left\{ (1) \right\}_{\Omega} = \sin(10 \theta^2), \left\{ (2) \right\}_{\Omega} = \sin(10 \theta^1 \theta^2), \left\{ (2) \right\}_{\Omega} = 0, \left\{ (2) \right\}_{\Omega} = 0, \left\{ (n) \right\}_{\Omega} = \sin(10 \theta^1 \theta^2) \).

A regular mesh obtained by uniform subdivision of the parameter space into \( 2 \times 2 = 4 \) elements represents refinement level 0. We get the subsequent refinement levels by uniform subdivision of the previous level. The results of the convergence study are depicted in Fig. 5. We observe optimal convergence rates, i.e. \( O(h^{p+1}) \)-convergence, where \( h \) is a characteristic element length.

#### 4.2 Verification example for an implicitly defined shell

The implementation of the FEM for an implicitly defined shell is verified. To this end, we consider a manufactured solution on a torus. The geometry of the considered surface is defined by the zero level-set of the function
\[ \phi(x, y, z) = d(x, y, z) = \sqrt{(\sqrt{x^2 + z^2} - R)^2 + y^2} , \]  
\[ r = 0.4, \quad R = 0.8 , \]  
\[ (36) \]
\[ \mathbf{x} = \mathbf{x} - d \nabla d \]  

is explicitly available, which maps \( \mathbf{x} \in \mathbb{R}^3 \) to a point \( \mathbf{X} \in \hat{\mathcal{O}} \) on the reference surface. Thus, a point \( \mathbf{x} \) has the decomposition \((x, d)\). This allows us to adapt (15) to

\[ \tilde{\mathbf{u}}(\mathbf{X}) = V_b(d) \left( u_1^{(1)}(\mathbf{x}) \mathbf{e}^i + u_2^{(2)}(\mathbf{x}) \mathbf{e}^j + V_n(d) u_n^{(n)}(\mathbf{x}) \nabla d \right), \]

(38)

since \( \mathbf{n} = \nabla d \). With the displacement field given in (38), the source terms follow easily from the relations in (12). We remark that we have checked the convergence for different displacement fields. Here, we present the results for the prescribed solution

\[ u_1^{(1)} = u_1^{(2)} = (0.3 - x) z (1.1 - z). \]

(39)

Again, we study the convergence rates under uniform mesh refinement. We remark that, because of the mapping of \( \hat{\mathcal{O}}_h \) to \( \hat{\mathcal{O}} \) used in the method, it is sufficient to subdivide the triangles of \( T_h \) in a refinement step. Thus, for all refinement levels \( \hat{\mathcal{O}}_h \) is the one and the same surface. The results of the convergence study are given in Fig. 7. We observe optimal convergence rates.

### 4.3 Pinched hemisphere

In this example, we consider the pinched hemisphere problem in order to test the suggestion how to handle a singular parametrization. This example is taken from the popular shell obstacle course [4]. The reference surface is described by

\[ x = \cos \theta^1 \cos \theta^2, \]
\[ y = \sin \theta^1 \cos \theta^2, \]
\[ z = \sin \theta^2, \]

(40)

and \( (\theta^1, \theta^2) \in [0, 2\pi] \times [0, \pi/2] \). This parametrization fulfills the assumptions in Sect. 3.1. The material properties and the general problem setup are shown in Fig. 8. The edge of the hemisphere is unconstrained and the four radial forces have alternating signs such that the sum of the applied forces is zero. We investigate the radial displacement at the loaded points. In [4], the reference displacement of \( u_r = 0.0924 \) is given. Our results are given in Table 1.

Obviously, the low order methods underestimate the displacement significantly for the considered meshes. This is expected as the low order elements (linear, quadratic, cubic) can only poorly represent rigid body rotations and are affected by locking. However, the high order methods (quartic and higher) converge quickly. We further investigate the ability to represent rigid body motions by inspection of the
Fig. 6 Triangulations for the deformed torus example: the base triangulation (upper left), the mapped triangulation (upper right), side view (lower left), and top view (lower right).

Fig. 7 Convergence results for the implicitly defined shell. Refinement level 0 is the base triangulation.

Eigenvalues of the stiffness matrix. The three rigid body translations can be represented exactly by the elements, resulting in three zero (up to numerical round-off errors) eigenvalues. As the rigid body rotations are only approximated the next three eigenvalues are nonzero. The sixth smallest eigenvalues for different meshes and polynomial orders are given in Table 2. As expected they decrease rapidly with increasing polynomial order.

Furthermore, we have solved the pinched hemisphere with the implicit formulation. The triangulations shown in Fig. 9 have been used. As an input we have given the four element triangulation where all vertices are on the reference surface. All other meshes have been obtained by uniform refinement. In contrast to a classical method, there is no need to better approximate the geometry by these triangulations, since they are mapped to the exact geometry within the method. In Table 3 the computed radial displacements at the loaded points are given. These results are similar to the results obtained by the parametric method given in Table 1.

4.4 Scordelis-Lo roof

We consider the Scordelis-Lo roof problem, which is also an example from the shell obstacle course [4]. It is a popular benchmark test to assess the performance of finite elements regarding complex membrane strain states. The cylindrical roof (radius $r = 25$) is supported by rigid diaphragms at the ends ($x = 0$ and $x = 50$), i.e., $u_y = u_z = 0$. All other surfaces are free. The geometry and the material parameters are depicted in Fig. 10. The structure is subjected to gravity loading with $b = -e_3 \cdot 360$. For the parametrization of the reference surface, we use
**Fig. 8** Problem description of the pinched hemisphere problem

\[ E = 6.825 \times 10^7 \]
\[ \nu = 0.3 \]
\[ R = 10 \]
\[ t = 0.04 \]
\[ F = 2 \]

\[ x = 50 \kappa (\theta^2), \]
\[ y = 25 \sin \left( \frac{40\pi \kappa (\theta^1)}{180} \right), \]
\[ z = 25 \cos \left( \frac{40\pi \kappa (\theta^1)}{180} \right), \]

with the function

\[ \kappa (\tau) = \tau \left( (3 - 2\tau)\tau + b(1 - 3\tau + 2\tau^2) \right) \]

with \( b = \frac{1}{100} \).

We use the function \( \kappa \) in order to capture the boundary layer. It has the properties \( \kappa(0) = 0, \kappa(1) = 1, \kappa'(0) = \kappa'(1) = b \) and is illustrated in Fig. 11. The parameter space is given by \( \theta^1 \in [0, 1] \) and \( \theta^2 \in [0, 1] \). In Fig. 10, a \( 16 \times 16 = 256 \) element mesh mapped to the real space is illustrated.

We study the vertical displacement of point \( A \), which is located in the middle of one free edge and on the mid-surface. We remark that the vertical displacement varies considerably through-the-thickness. The results for different ansatz orders and meshes are given in Table 4. It is evident that the low order methods are affected by locking. The results obtained with linear ansatz functions are far from the converged solution \( u_z = -0.3014 \). Raising the ansatz order reduces the locking

---

4.5 Gyroid

In this example, we consider the deformation of a shell structure where the reference surface is part of a gyroid, see Fig. 12. An approximation of a gyroid is given by the level-set function

\[ \phi(x, y, z) = \sin(x) \cos(y) + \sin(y) \cos(z) + \sin(z) \cos(x). \]

The considered shell lies in \( B = [0, 2] \times [-0.5, 0.5] \times [-0.5, 0.5] \). The shell structure is fixed at the plane \( x = 0 \). We assume a thickness \( t = 0.03 \).

We study the static deformation due to a volume load \( b = e_z \cdot 10^7 \). To this end, we use three different surface meshes, which are depicted in Fig. 13. The coarsest mesh is obtained by the Marching Cubes Algorithm [26] and mesh smoothing. The other two meshes are obtained by uniform refinement of the coarsest mesh. We remark that, in the analysis, each mesh is mapped to the exact surface by means of (28). Table 5 illustrates the convergence of the vertical displacement \( u_z \) at the point \([2, 0.5, -0.25]\). Obviously, the results obtained by linear ansatz functions underestimate the deformation tremendously for the considered meshes. The use of quadratic ansatz functions reduces the locking considerably. In view of the results obtained by the octic ansatz functions, we can accept a converged value of \( u_z = 1.8812 \).

5 Conclusion

In this paper, high order finite element methods for shell analysis have been presented. The underlying shell model is a displacement based seven-parameter model. As a special feature, the methods incorporate the exact geometry of parametrically and implicitly defined reference surfaces. We have shown the capabilities of the methods in five examples. In order to assess the convergence behavior, the method of manufactured solutions has been utilized. In all numerical

Fig. 12  Geometry of the gyroid problem

In the present work we used a purely displacement based formulation. Thus, various locking phenomena reduce the efficiency of the method when using low order approximations. In order to reduce locking phenomena, we have resorted to high order shape functions (our implementation allows for arbitrary high order). As this might be not very efficient in many examples, it would be interesting to develop low order locking-free elements based on the exact geometry in future work.

Moreover, the use of a seven-parameter shell model allowed us to use $H^1$-conforming ansatz and test spaces. This might not be appropriate for other shell models like Kirchhoff–Love type models or Reissner–Mindlin type models. In the former, typically, $H^2$-conforming elements are needed, whereas in the latter elements are necessary providing a vector field tangential to the surface. The development of such elements for implicitly defined shells should receive further attention.
