ABSTRACT: Four different samples of ordered mesoporous silica powders (MCM-41 and SBA-15) and amino-functionalized mesoporous silica (MCM-41-NH₂ and SBA-15-NH₂) were used to prepare modified glassy carbon electrodes coated with ion-exchange polymer Nafion to be used for the electrochemical detection of Cd(II). The mesoporous silica samples were characterized through transmission electron microscopy, small-angle X-ray scattering, and N₂-adsorption/desorption isotherms. The electrodes were characterized by using square wave anodic stripping voltammetry. The effect of pH and of the silica type on the electrodes’ response was investigated. The influence of amino functional groups grafted on the silica surface toward Cd(II) ion detection was also examined. The detection limits determined with the new silica-modified electrodes [between 0.36 and 1.68 μM Cd(II)] are slightly higher than those reported in the literature, but they are lower than those stipulated in the European legislation [45 μM Cd(II)] and, consequently, the electrodes could be successfully used to detect Cd(II) in aqueous solutions.

1. INTRODUCTION

Cadmium ion detection is of great interest because of their long half-life and accumulation in tissues and organs, mainly in kidneys and liver.¹ Cd(II) is essentially a cumulative poison exhibiting carcinogenic activity, and for these reasons, the measurement of cadmium is important in clinical and toxicology laboratories. Electrochemical detection of Cd(II) has great potential for environmental monitoring of toxic metal ions because of the portability of electrodes and their excellent detection limits (DLs). The detection can be carried out by using mainly anodic stripping voltammetry with different modified electrodes: carbon paste electrodes modified with zirconium-phosphated silica,¹ diaetylhydrazine,² zeolites,³,⁴ carbon nanotubes,⁵ conducting polymers,⁶ and so forth; bismuth-modified carbon electrodes,⁷–¹³ silica-modified electrodes,¹⁴–¹⁷ and many others.¹⁸,¹⁹

Ordered mesoporous silica (OMS) materials have widely been investigated for several applications. Since their discovery in the 1990s,²⁰ they have been used for catalysis,²¹,²² biocatalysis,²³–²⁶ adsorption,²⁷,²⁸ and as drug delivery carriers.²⁹–³² The main goal of these materials is due to their large specific surface area and highly uniform pore size. Despite their low conductivity, OMSs can be used for electrode material preparation because of their high adsorption capacity and large specific surface area, which could be advantageously exploited in the preconcentration of electroactive analytes before their electrochemical detection.³³ As nonconductors, OMSs do not contribute to the charging current when they are used as electrode modifiers, thus leading to low background.³⁴ On the other hand, silica-based mesoporous materials can be grafted with a large variety of organic functionalities, which prevent their leaching from the electrode surface, leading to a good stability of the electrodes, or facilitate the electrode reaction. In this context, we recently compared SBA-15 and MCM-41 as matrices for the modification of glassy carbon (GC) electrodes for the voltammetric detection of malachite green.³⁵

In this work, four different OMS powders belonging to two different classes (MCM-41 and SBA-15) were used to prepare modified GC electrodes coated with Nafton to be used for the electrochemical detection of Cd(II) ions. The influence of the silica type and its characteristics on the electrochemical response of the modified electrodes was investigated by using square wave anodic stripping voltammetry (SWASV) at two pH values (6 and 4.4). In order to better understand the differences between the electrochemical behavior of the electrodes fabricated with different types of silica, the role of amino functional groups grafted on the silica surface in the Cd(II) ion detection was also examined.

2. RESULTS AND DISCUSSION

2.1. Synthesis and Characterization of OMS Samples. The synthesized mesoporous silica materials, MCM-41 and SBA-15, were functionalized with aminopropyl-triethoxysilane to obtain the aminopropyl-functionalized MCM-41-NH2 and SBA-15-NH2 samples. The four samples were then characterized through N2-physisorption isotherms, small-angle X-ray scattering (SAXS), and transmission electron microscopy (TEM). The N2-physisorption isotherms of MCM-41, SBA-15, and the relative amino-functionalized samples are shown in Figure 1A. MCM-41 and MCM-4-NH2 (type IV) isotherms show an increase of N2 volume adsorption at a relative pressure between 0.2 and 0.4 p/p0. The isotherms are reversible and do not show any appreciable hysteresis loop. SBA-15 and SBA-15-NH2 also exhibit a type IV isotherm, with a sharp increase of N2 volume adsorption at the relative pressure of p/p0 = 0.6–0.7, as expected considering their wider pores with respect to those of MCM-41-based materials. In this case, a H1 hysteresis cycle due to the capillary condensation of nitrogen into the mesopores occurs. The SBA-15-NH2 curve is shifted toward low adsorbed nitrogen volumes with respect to that of SBA-15.

2.2. Influence of pH and of Silica Type. The effect of the nature of the silica types on the voltammetric response of the silica-modified electrodes toward Cd(II) detection was investigated at two pH values (4.4 and 6). By anodic stripping voltammetry (SWASV), the analyte of interest is electro-deposited on the working electrode during a reduction step and then oxidized from the electrode during the stripping step, the resulting current being measured. Thus, for Cd(II) detection by SWASV, a first step of preconcentration was operated at −1.3 V versus Ag/AgCl,KCl sat during an accumulation time of 120 s, which was chosen after preliminary experiments as the optimal deposition time. The performance of each silica type in the same experimental conditions was evaluated and discussed. The SWASV responses are presented in Figure 2.

It can be observed that at both pH values, the peak currents increase significantly at silica-modified electrodes. This is certainly due to the increase of the electrode-specific surface area in the presence of silica and to its ability to adsorb electroactive species during the accumulation step. Additionally, a broadening of the peaks is noticed, especially at higher concentrations of Cd(II) (Figure 3). A possible explanation could be a sluggishness of the electrode kinetics or interactions between adsorbed species that may be expected to become more significant as the surface coverage increases.

| sample   | S BET (m2/g) | dPeb,BJH (Å) | V cdes,BJH (cm3/g) | dV (Å) |
|----------|-------------|--------------|-------------------|------|

Table 1. Characteristics of the Various Mesoporous Silica Samples
that at more acidic pH values the electron transfer takes place more easily.

As expected, the height of the oxidation peak of Cd increases with its concentration, leading to a calibration curve where a linear domain at low concentration of Cd(II) can be identified (see as example Figure 3 for the GC/SBA-15-NH$_2$/Na$_x$on electrodes at pH 6).

2.3. Calibration Curves and Electroanalytical Parameters. The calibration curves corresponding to all modified electrodes at the beginning of their linear domain are presented in Figure 4. In fact, the different modified electrodes showed different linearity ranges, which depend on both the OMS sample and the operational pH, as reported in Table 3. Table 3 also reports other electroanalytical parameters as, for example, the DLs, which were calculated for a signal-to-noise ratio of 3, using the formula:

$$
\text{DL} = \frac{3\text{SD}}{\text{slope}},
$$

where the slope and standard deviation (SD) correspond to the parameters of the fitting equation.

All silica powders have a good impact on the detection of metal ions because of their adsorption properties. At both tested pH values, the DL is smaller for GC/SBA-15-NH$_2$/Na$_x$on than for GC/SBA-15/Na$_x$on electrodes, which suggests a better efficiency to detect Cd(II) of the first ones. The effect is more pronounced at pH 6. It is probable that amino groups bind metal ions, increasing their concentration at the interface and hence lowering the DLs.

The effect of pH is less remarkable in the case of GC/MCM-41-NH$_2$/Na$_x$on and GC/MCM-41/Na$_x$on electrodes. A decrease of DL at the GC/MCM-41-NH$_2$/Na$_x$on electrode is noticed at pH 6, but no significant differences of sensitivities and DLs were noticed between MCM-41 and MCM-41-NH$_2$.

### Table 2. Oxidation Potentials for Cd at Various Silica-Modified Electrodes at pH 4.4 and 6

| Electrode Types | E/V vs Ag/AgCl, KCl$_{sat}$ |
|-----------------|-----------------------------|
|                 | pH 4.4 | pH 6 |
| GC/Na$_x$on     | −0.734 | −0.760 |
| GC/SBA-15/Na$_x$on | −0.751 | −0.809 |
| GC/SBA-15-NH$_2$/Na$_x$on | −0.728 | −0.778 |

As expected, the height of the oxidation peak of Cd increases with its concentration, leading to a calibration curve where a linear domain at low concentration of Cd(II) can be identified (see as example Figure 3 for the GC/SBA-15-NH$_2$/Na$_x$on electrodes at pH 6).
at pH 4.4. It should also be mentioned that despite its smaller specific surface area, the SBA-15-NH₂ sample was proven to be more performing than MCM-41-NH₂ in which the DL is concerned. From data listed in Table 3, we also observe that the electrode sensitivity depends both on the type of silica and on the solution pH. SBA-15-NH₂ has a higher sensitivity at both pHs than the unmodified SBA-15 (approximately four times higher at pH 6 and three times higher at pH 4.4). This could be due to the fact that at pH 6, the coordination of Cd(II) by amino groups is the driving mechanism and, at pH 4.4, the protonation of −NH₂ groups may decrease cadmium coordination. Even if the DL values are higher than those reported by other authors,1 the proposed electrodes could be successfully used to determine Cd(II) in industrial sources of heavy metals, such as industrial wastewater and sewage sludge, where the concentration of Cd(II) could be relatively high.

2.4. Reproducibility and Repeatability. Reproducibility of the GC/SBA-15-NH₂/Nafion electrode was assessed at pH 6 on four consecutive measurements of 10 μM solution of Cd(II) and the mean value of the obtained peak current was 1.828 × 10⁻⁵ A, with a relative SD (RSD) of 5.87%. Repeatability was tested on three different electrodes in the same 4 μM Cd(II) solution and the mean value of the obtained peak current was 6.304 × 10⁻⁶ A, with an RSD of 1.90%.

2.5. Real Sample Analysis. Determination of Cd(II) concentration was performed by SWASV, with the GC/SBA-15-NH₂/Nafion electrode, on a natural underground water sample, collected by drilling from a site situated in Salaj district (Romania). The peak height value, measured three times (with the same electrode) and mediated, was interpolated on a premade calibration curve, and the concentration was determined. The calibration curve was done on a 0.5–10 μM Cd(II) concentration range, at pH 6 (considering that the pH of the water sample was 5.5, determined before the SWASV measurement), under the same working conditions as all SWASV measurements before (for experimental conditions, see Figure 3).

The performances of the proposed electrochemical method of detection for Cd(II) were compared against the standard F-AAS method, with results presented in Table 4. As observed, the agreement between the results obtained by the two methods was very good. By using the silica-modified electrode, the Cd(II) concentration was found to be 98.09% from the standard F-AAS method.

3. CONCLUSIONS

Four different mesoporous silica powders were used to prepare modified GC electrodes coated with ion-exchange polymer Nafion to be used for the electrochemical detection of Cd(II). The silica powders have a good impact on the detection of metal ions because of their adsorption properties. The large specific surface area of silica powders certainly plays a key role in their performance, but in some cases, the most important is the effect of the −NH₂ groups, which have a beneficial influence, most probably because of the complexation possibility of cadmium ions. Other characteristics could also be taken into consideration. The electrodes’ analytical performances increase in the series: GC/SBA-15/Nafion (pH 4.4 and 6) < GC/MCM-41/Nafion (pH 6) < GC/MCM-41-NH₂/Nafion (pH 4.4) < GC/MCM-41-NH₂/Nafion (pH 4.4 and 6) < GC/SBA-15-NH₂/Nafion (pH 4.4) < GC/SBA-15-NH₂/

Nafion (pH 6). Even though the DL values determined with the new silica-modified electrodes are slightly higher than those reported in the literature, the electrodes are easy to prepare and could successfully be used to detect Cd(II) in real aqueous solutions.

4. EXPERIMENTAL SECTION

4.1. Chemicals. Tetraethoxysilane (98%), hexadecyltrimethylammonium bromide (CTAB, >99%), Pluronic copolymer 123 (EO20-PO20-EO20), sodium hydroxide, anhydrous tolune (99.8%), APTES (>98%), triethylamine (>99%), and hydrochloric acid (37%) were purchased from Sigma-Aldrich (Milan). A 0.1 M phosphate buffer solution was prepared from Na2HPO4 and NaH2PO4 (Merck, Darmstadt, Germany). The pH of the buffer solutions was adjusted to the desired values by adding H3PO4 solution (Merck, Darmstadt, Germany). Sodium dodecyl sulfate (SDS) and Nafion (5% in ethanol) solution were purchased from Sigma-Aldrich. Distilled water was used for preparing all solutions. All reagents were of analytical degree and were used without further purification.

4.2. Synthesis, Functionalization, and Characterization of OMS Samples. MCM-41 and SBA-15 samples were synthesized according to the procedures reported in refs 39 and 40, respectively. The organic surfactants, either CTAB or Pluronic 123, were removed by calcination at 550 °C for 3 h. The functionalized MCM-41-NH2 (SBA-15-NH2) was prepared by adding 1 mL of APTES to a suspension of 1 g of MCM-41 (SBA-15) in 30 mL of anhydrous tolune. The mixture was heated under reflux for 15 h. The resulting solid was filtered and washed with acetone and dried overnight under vacuum at room temperature.31 Textural analysis was carried out on an ASAP 2020 instrument by determining the N2-adsorption/-desorption isotherm at 77 K. Before analysis, MCM-41 and SBA-15 samples were heated at 250 °C at a rate of 1 °C/min under vacuum for 12 h, whereas MCM-41-NH2 and SBA-15-NH2 were heated at 110 °C at the rate of 1 °C/ min under vacuum for 24 h. The Brunauer–Emmett–Teller (BET)32 and Barrett–Joyner–Halenda (BJH)42 methods were used to calculate the specific surface area and pore size distribution (from the desorption branch), respectively. SAXS patterns were recorded by means of a S3-MICRO SWAXS camera system (HECUS X-ray Systems, Graz, Austria). Thin-walled 2 mm glass capillaries were filled with the sample for the scattering experiments and analyzed under the same conditions reported in ref 26. TEM images were obtained on a JEOL 100S microscope, and finely ground samples were placed directly onto formvar-coated electron microscopy nickel grids.

4.3. Preparation of GC/Silica/Nafion-Modified Electrodes. Before conducting any measurements, the GC working electrode was cleaned thoroughly on a piece of felt with γ-alumina paste until mirror-like shine was obtained. It was subsequently washed in an ultrasound bath with distilled water to rinse off any trace of alumina. Mesoporous silica suspensions were stabilized by means of sodium dodecyl sulfate (SDS),35 which allowed to obtain a homogeneous suspension and to prevent precipitation and aggregation of silica particles. The suspensions (5 μL) were applied by drop-casting on the electrode’s active surface and dried. To improve stability, a coating with 5 μL of 0.5% Nafion was created using the same method.

4.4. Electrochemical Measurements. All electrochemical experiments were performed on a Metrohm Autolab PGSTAT 302N, electrochemical workstation (Eco Chemie, The Netherlands). A three-electrode system was used, composed of an Ag/AgCl, a KCl sat reference electrode, a platinum wire counter electrode, and a GC working electrode, bare or modified. The electrolyte solution was 0.1 M phosphate buffer (adjusted at pH 4.4 and 6). The two pH values were selected, according to literature data, in order to find the best working conditions, taking into account that the behavior of −NH2-containing silica powders is influenced by the acidity of the buffer solution. pH values above 6.0 can decrease the electrode signal noticeably, as Cd(II) ions would precipitate as hydroxide sediments.30 All experiments were performed at room temperature. Square wave voltammetry measurements were performed using a preconcentration time of 120 s at −1.3 V, followed by a potential stripping from −1.3 to −0.4 V, with a frequency of 25 Hz.

4.5. Real Sample Analysis. The real underground water sample was analyzed by F-AAS (atomic absorption spectrometry in flame) with a contrAA 800 F atomic absorption spectrometer. The analysis was repeated three times, and the results were mediated for comparison with the electrochemical method.
