The isovector giant dipole resonance (GDR) is perhaps the simplest example of a nuclear collective motion of all the protons against all the neutrons. Since its observation in the photo-absorption cross section [1], it has been intensively studied as it combines several challenging aspects of the physics of the atomic nucleus [2, 3]. Even though GDR is practically harmonic in character, it is not an adiabatic collective mode and various damping mechanisms of the collective energy are at work [4]. In the models of Migdal [5], Goldhaber-Teller [6], and Steinwedel-Jensen [7] GDR is described as the relative motion of two fluids, either compressible or incompressible, with neutrons and protons vibrating around a common center of mass, and the mass dependence of the excitation energy reads $A^{-1/6}$ and $A^{-1/3}$ respectively [8]. A good estimation of the GDR vibrational frequency is $\hbar \omega \approx 80$ MeV $A^{-1/3}$ for spherical nuclei. GDR is interpreted simply as the equivalent of the zero-sound in a nuclear system and the size of the nucleus sets a constraint on the largest wavelength. In the case of deformed nuclei, the GDR peak is split, with various frequencies revealing different principal axes of the nuclear shape. Since the GDR state is not an eigenstate of the nuclear Hamiltonian, it is characterized by a spreading width that cannot be extracted from a simple hydrodynamical approach. The spreading width in principle can be calculated within a microscopic model of the atomic nucleus. The total width of the GDR is mainly due to a couple of mechanisms: the coupling of the GDR to complex nuclear configurations $\Gamma^\dagger$, and the coupling to the continuum, leading to the escape of neutrons and protons $\Gamma^\dagger$. These two widths contribute to the total width of the GDR, $\Gamma = \Gamma^\dagger + \Gamma^\uparrow$, and their relative contributions vary depending on the mass number $A$ and the $N/Z$ ratio. The escape width is typically more important for light nuclei. The physical mechanisms related to $\Gamma^\dagger$ may be quite complicated and involve coupling to low energy surface vibrations, Landau damping and collisional damping [1].

The theoretical approach to GDR is typically within the linear response of the nuclear system to an external probe [9]. In contemporary approaches, the description of the atomic nucleus is provided by a Density Functional Theory (DFT) [10] and the GDR is described within the small amplitude limit of the time-dependent version of DFT. This approach leads to the well known (Quasiparticle) Random Phase Approximation (Q)RPA that has been used with a variety of nuclear density functionals, though only very recently for deformed systems, see Refs. [11-21] for several representative calculations. When applied to open-shell and, in particular, deformed nuclei QRPA requires diagonalizations of matrices of extremely large sizes and often severe truncations of the quasiparticle basis set. Truncations lead to a number of undesired features, in particular spurious states, instead of having a zero excitation energy, get admixed to transitions of physical interest. In a deformed open-shell nucleus, states corresponding to the excitation of the center of mass motion, rotation of the system, and gauge transformations arising from the breaking of the proton and neutron number conservations, all have zero-energy excitation energy (sometimes referred to as Goldstone modes). When (Q)RPA is derived, one usually allows for small violations of the Pauli principle, which have only a negligible effect when one is considering the most collective transitions. (Q)RPA formally is an approach in which the fermionic nuclear Hamiltonian is bosonized and the number of bosonic excitations allowed to exist is significantly much larger than the number of true physical excitations. Significant difficulties arise when one tries to go beyond the (Q)RPA and consider coupling to more complex configurations, and describing the spreading width $\Gamma^\dagger$. In spite of the efforts of many generations of theorists and many approaches suggested so far (nuclear field theory [22], boson expansion methods [8, 23], and diagrammatic methods [4]), a truly satisfactory mi-

(Dated: February 1, 2013)

A fully symmetry unrestricted Time-Dependent Density Functional Theory extended to include pairing correlations is used to calculate properties of the isovector giant dipole resonances of the deformed open-shell nuclei $^{172}$Yb (axially deformed), $^{188}$Os (triaxially deformed), and $^{238}$U (axially deformed), and to demonstrate good agreement with experimental data on nuclear photo-absorption cross-sections for two different Skyrme force parametrizations of the energy density functional: SkP and SLy4.

PACS numbers: 21.60.Jz, 23.20-g, 24.30.Cz, 25.20.Dc
crosscopic treatment is still lacking and theorists resort to either phenomenological models, such as optical potentials (which can easily lead to overestimates of $\Gamma$ unless vertex corrections are accounted for as well [4]), or simple prescriptions such as adding a popular, but arbitrary, energy smoothing of the (Q)RPA strength.

Here we present an approach to GDR in open-shell nuclei based on an extension of the DFT to superfluid systems, superfluid local density approximation (SLDA) and its further extension to time-dependent phenomena (TD-SLDA), which was developed over the years and applied to a number of physical systems and phenomena, see Refs. [24,25]. The time-dependent Hartree-Fock-Bogoliubov (TDHF) approximation has been previously shown as an alternative to QRPA in spherical nuclei [36] and with a number of further approximations in deformed nuclei [37,38]. TDSDLDA appears formally as a time-dependent self-consistent local mean-field approximation. No spurious modes are admixed to physical transitions, since the energy density functional respects all the required symmetries (translational and rotational symmetry, Galilean invariance [39], parity, isospin symmetry, gauge symmetry) and no further approximations are introduced, apart from discretization errors which are under control. Isospin symmetry is broken only by the proton/neutron mass difference and by the Coulomb energy, which we treat in the Hartree approximation. We use an approximation to the normal part of the nuclear energy density functional provided by various Skyrme force parametrizations [40,42] and all the terms are taken into account numerically exactly. The pairing part of the energy density functional is treated as described in Ref. [24] and [25], when a single coupling constant is used for both protons and neutrons, and even and odd particle numbers as well, unlike most phenomenological approaches to nuclear pairing which break isospin invariance in the pairing channel. In such approaches, see Refs. [12] and [13] for examples of QRPA calculations, the proton pairing constant is larger in magnitude than the neutron pairing coupling constant, $|V_p| > |V_n|$. This leads to a flagrant violation of isospin invariance in the energy density functional, the magnitude of which is clearly not due to charge-symmetry-breaking forces. Such effective pairing couplings would be consistent with a new kind of pairing energy, that does not violate charge symmetry breaking [43]. The Coulomb interaction will lead to just an opposite relation [44, namely to $|V_p| < |V_n|$. Galilean invariance [39] requires the presence of currents in the energy density functional, and although their contribution is vanishing in the ground states of even-even nuclei, it is important for the excited states [45,46].

Within TDSLDA one describes accurately the interaction in both particle-hole and particle-particle channels, the treatment is fully self-consistent, and all symmetries of the Hamiltonian are properly accounted for. We place the nuclear system on a 3D spatial lattice, needed spatial derivatives are determined using Fast Fourier Transform, and we at first determine the ground state properties within SLDA and subsequently subject the system to an external time-dependent one-body potential [33,35,47]. The Coulomb interaction is treated with particular care, so as not to introduce the potential due to image charges, which appear naturally in a spatial lattice formulation with periodic boundary conditions. Although we study the small amplitude limit, the equations we solve here are the same as for a motion of arbitrary amplitude. The emerging equations are formally equivalent to the TDHF approximation with local potentials, or to the time dependent Bogoliubov-de Gennes (TDBdG) equations:

$$\begin{pmatrix}
\hat{u}_{k\uparrow} \\
\hat{u}_{k\downarrow} \\
\hat{v}_{k\uparrow} \\
\hat{v}_{k\downarrow}
\end{pmatrix} =
\begin{pmatrix}
h_{\uparrow\uparrow} & h_{\uparrow\downarrow} & 0 & \Delta \\
h_{\downarrow\uparrow} & h_{\downarrow\downarrow} & -\Delta & 0 \\
0 & -\Delta^* & -h_{\uparrow\uparrow}^* & -h_{\downarrow\downarrow}^* \\
\Delta^* & 0 & -h_{\uparrow\downarrow}^* & -h_{\downarrow\uparrow}^*
\end{pmatrix}
\begin{pmatrix}
\hat{u}_{k\uparrow} \\
\hat{u}_{k\downarrow} \\
\hat{v}_{k\uparrow} \\
\hat{v}_{k\downarrow}
\end{pmatrix},$$

where we have suppressed the spatial $r$ and time coordinate and $k$ is the label of each quasiparticle wave function $|u_{\sigma}(r,t), v_{\sigma}(r,t), \rangle$, where $\sigma = \uparrow, \downarrow$. The single-particle Hamiltonian $h_{\sigma\sigma'}(r,t)$ is a partial differential operator (thus local) and $\Delta(r,t)$ is a pairing field, all defined through the normal, anomalous, spin, and isospin densities and currents. The interaction with various applied external fields (spin, position and/or time-dependent) is described by including the corresponding potentials in the single-particle Hamiltonian $h_{\sigma\sigma'}(r,t)$. This approach represents a flexible tool to describe in general large amplitude nuclear motion as it contains the coupling to the continuum and between single-particle and collective degrees of freedom, since the meanfield is explicitly time-dependent. However, the later type of coupling between single-particle and collective degrees of freedom will account only for a part of the diagrams discussed in Ref. [4]. If the external field will act along one of the symmetry axes for example, only collective oscillations along that axis will be excited, but not in the perpendicular direction. Although the TDSLDA is designed to provide the values of one-body densities, a simple modification of the variational principle extends the approach to two body observables, for example, particle number fluctuation [48,52]. Another straightforward extension of the formalism leads to the stochastic TDSLDA, with hopping between various time-dependent meanfields, and can account for dissipation [53].

The most convenient quantity for studying the GDR is the strength distribution: $S(E) = \sum_{\nu} |\langle \nu | F(0) | \nu \rangle|^2 \delta(E - E_{\nu})$, where $\{|\nu\rangle\}$ are nuclear eigenstates corresponding to energies $E_{\nu}$. In our case the operator $\hat{F}$ is a sum of two operators depending on neutron and proton coordinates, respectively: $F_{\tau}(r) = N_{\tau} \sin(k \cdot r)/|k|$, where $\tau = n, p$, $|k| = 2\pi/L$, $L$ is a lattice size of the box, $N_n = -Z, N_p = N$ are neutron and proton numbers, respectively and $A = N + Z$. The operator $F_{\tau}(r)$ generates all the odd multipoles, but the predominant contribution...
comes from the dipole mode. In practice, depending on
the symmetry of the ground state, we calculate the re-
response of the nucleus to different external fields. Thus,
for a spherical nucleus, we can choose \( r_p \) and \( r_n \) along any
direction, for an axially deformed nucleus we compute two
different responses with \( r_p \) and \( r_n \) along two sym-
metry axes, while for a triaxial nucleus we compute the
responses along three principal axes. Within our formal-
ism, the external perturbation is added to the Hamilton-
ian \( h_{\tau,\sigma}(r,t) \Rightarrow h_{\tau,\sigma}(r,t) + F_r(r)f(t) \) and switched on
adiabatically, where \( f(t) = C \exp[-(t - 10)^2/2] \) (time in
units of \( \text{fm}/c \)) and \( C \) defines the intensity of the perturba-
tion and which has to be kept sufficiently small to stay in
the linear response regime, but large enough to excite the
modes of interest. The amount of energy deposited into
a nucleus was in the range 45-50 MeV. For such perturba-
tions, which imply harmonicity of the excitation, the re-
sponse function to the external perturbation \( \delta F(t) \) is
given by \( \delta = 2 \pi f(\omega)/|\pi f(\omega)| \); where \( \delta \) is the Fourier transform of the fluctuation of the expec-
tation value: \( \delta F(t) = \langle \delta F \rangle_t - \langle \delta F \rangle_0 = \int d^3r \delta \rho(r,t) F(r) \). The extraction procedure of the strength function is sim-
ple to state: obtain the self-consistent stationary solu-
tion using the stationary SLDA solver to high precision
so the spurious contributions due to global excitations
(center-of-mass motion, rotations for deformed nuclei, pro-
ton and neutron pairing Goldstone modes) are de-
coupled, and subsequently use this solution as input for
the TDSLDA code where it is perturbed by the exter-
nal field and evolved for a period of time, \( T \). The
energy resolution due to taking the Fourier transform in
the finite window \( T \) is \( \delta E = 2\pi h/T \), and so it is im-
portant to perform propagation to sufficiently large \( T \)
(here \( T \approx 1600 \text{ fm}/c \) and \( \delta E \approx 0.8 \text{ MeV} \)). We have used a
cubic lattice box with \( L = 32.5 \text{ fm} \) on a side and a
lattice constant 1.25 fm, which allows us to obtain the
ground-state energy with an accuracy of a few tens of
kilo-electron-volts for a number of spherical light open-
shell nuclei. The TDSLDA equations were integrated in
time using a fifth order multistep method with a time
step \( \Delta t \approx 0.12 \text{ fm}/c \) chosen to maintain a \( 10^{-7} \)
relative accuracy, see Refs. \[33\] \[35\]. The changes in proton
and neutron numbers during the time evolution change are
\( |\Delta Z| < 10^{-4} \) and \( |\Delta N| < 10^{-4} \) respectively. TD-
SLDA, when the external perturbation does not change
the particle number, as in the GDR case, the particle
number in the time-dependent solution is exactly con-
served, and thus all the excited modes have exactly the
same average proton and neutron particle number as the
ground state. The method recently suggested in Ref.
\[17\], with the technical improvements described in Ref.
\[18\], has the promise to become the leading approach for
QRPA calculations in open-shell nuclei, because of the
simplicity of its numerical implementation and its accu-
rracy. The solutions of the QRPA however are harder to
interpret \[11\], since for a given nucleus these equations
will provide solutions for \( \Delta N = 0, \Delta Z = 0 \), as well as
pairing vibration type transitions with \( \Delta N = \pm 2 \) and/or
\( \Delta Z = \pm 2 \) respectively. TDSLDA has been applied so far
to describe excitations with no change in particle number
\( \Delta N = 0 \) due to time-dependent external fields which do
not change the particle number \[33\] \[34\], as well as excita-
tions with \( \Delta N \neq 0 \) \[31\] in the case of more complicated
time-dependent external probes.

From the TDSLDA solutions we construct the occupation
probabilities for both proton and neutron quasiparticle
states:

\[
n_k(t) = \sum_{\sigma = \uparrow, \downarrow} \int d^3r |v_{k,\sigma}(rt)|^2,
\]

where \( k \) labels the proton and neutron quasiparticle wave
functions respectively. Because of the complexity of the
QRPA equations two types of approximations have been
often used in the past in the literature. In one kind of
approximation the proton and neutron densities are con-
structed from

\[
v_k(r, \sigma, t) = \sqrt{n_k(t)} \phi_k(r, \sigma, t),
\]

where \( \phi_k(r, \sigma, t) \) satisfy TDHF-like equations. The occupation
probabilities \( n_k(t) \) are obtained either in a TD-
BCS formalism, or are simply assumed to be frozen at
their ground-state values. One can easily show that in
the case of TDBCS the continuity equation is not satis-
fied \[54\], and thus particle number conservation is vi-
olated. The assumption that occupation probabilities are
frozen to their ground-state values is violated strongly as
well, as the two plots in Fig. \[1\] here amply demonstrate.
A typical example of this frozen occupation probabilities
approximate approach is in Ref. \[55\], in which one can
find a calculation of the GDR in the triaxial nucleus \[188\]Os
with SLy6, which is very similar to SLy4. The shape of
the GDR line shape calculated in Ref. \[55\] is noticeably
different from both the experimental one and our results;
see Fig. \[2\]. We notice that there are experimental indica-
tions that a pygmy resonance exists in the nucleus \[172\]Yb
\[54\]. We did not find any evidence of a pygmy resonance
using either of the two Skyrme energy-density functional
parametrizations SLy4 and SkP, and neither did Terasaki
and Engel using SkM* \[12\]. In Ref. \[12\] pairing corre-
lations were treated using a sharp cutoff, a prescription
that shows a strong dependence on the cutoff energy, at
least in the case of low-lying states \[57\]. The approach
adopted by us is free of such cutoff dependency in the
pairing channel, once the cutoff energy is chosen roughly
above 50 MeV \[24\].

In Fig. \[2\] we show the results of our calculations and
compare them with experimental data \[58\]. For the axi-
ally deformed nuclei, we performed two calculations per-
turbing the systems along the longer and the shorter axis,
respectively. The triaxial nucleus \[188\]Os required three
runs accordingly. The experimental data include sev-
eral effects: the coupling of the collective strength to the
$1p-1h$ states, especially to the low-lying collective vibrations, Landau damping ($\Gamma_L \approx \hbar v_F/R$, where $v_F$ is the Fermi velocity and $R$ the nuclear radius), particle escape into the continuum ($\Gamma^\dagger$), and coupling to more complex states ($\Gamma^\dagger$). The theoretical Thomas-Reiche-Kuhn sum rule for these nuclei are: 2.49 ($^{172}$Yb), 2.81 ($^{188}$Os), and 3.38 ($^{238}$U) in MeV-barn respectively. The corresponding energy integrated photo-absorption cross-sections in the interval 8- to 20-MeV are: 2.47, 2.73, and 3.06 in experiment, 1.94, 2.26, and 2.49 for SkP, and 1.84, 2.01, and 2.35 for SLy4 respectively. Both SkP and SLy4 forces underestimate the energy integrated cross-section in this energy interval, even though both Skyrme parametrizations adequately reproduce the average peak position and even the width, in spite of great difference in the isoscalar nucleon effective mass $m_{is}^* = m$ and $m_{is}^* = 0.7 m$, but very similar isovector effective mass, $m_{iv}^* = 0.74 m$ and $m_{iv}^* = 0.8 m$ for SkP and SLy4 respectively. The use of periodic boundary conditions forced us to use $|k| = 2\pi/L$ in $F_\tau(x) = N_\tau \sin(k \cdot r_\tau)/|k|$, instead of $|k| \rightarrow 0$, which leads to an underestimate of the cross-sections by $\approx 25\%$. With this trivial correction (obtained by calculating the energy weighted sum rule for the external probe we obtain 2.63(6) ($^{172}$Yb), 3.11(7) ($^{188}$Os), and 3.55(8) ($^{238}$U) for SkP and 2.50(5) ($^{172}$Yb), 2.77(5) ($^{188}$Os), and 3.35(8) ($^{238}$U), with the SLy4 results being in slightly better agreement with experimental results. The mixing with more complex configurations ($T^4$), will lead to some depletion of the transition strength out of this energy interval.

We thank G.F. Bertsch and T. Nakatsukasa for discussions and P.-G. Reinhard for literature leads. This work was supported by U.S. DOE Grants No. DE-FG02-97ER41014, No. DE-FC02-07ER41457, and No. DE-AC05-76OR01830 (KJR), and the Polish Ministry of Science under Contract No. N202 128439. Calculations have been performed on University of Washington Hyak cluster (NSF MRI Grant No. PHY-0922770), Franklin (Cray XT4, NERSC, DOE Grant No. B-AC02-05CH11231), and JaguarPF (Cray XT5, NCCS, DOE.

FIG. 1. (Color online) The time-dependent proton and neutron occupation probabilities of a set of quasiparticle states around the Fermi level for $^{238}$U calculated as described in the main text with an approximate energy density functional using the SLy4 parametrization.

FIG. 2. (Color online) The calculated photo-absorption cross-section (solid black line), using two Skyrme force parametrizations for three deformed open-shell nuclei and the experimental $(\gamma,n)$ cross-sections (solid purple circles with error bars), extracted from Ref. [58]. With dashed (green), dotted (red) and dotted-dashed (blue) lines we display the contribution to the cross-section arising from exciting the corresponding nucleus along the long axis, the short axis (multiplied by 2 for the prolate nuclei $^{172}$Yb and $^{238}$U) and the third middle axis in the case of the triaxial nucleus $^{188}$Os.
