Abstract. Parathyroid adenoma with prominent lymphocytic infiltrate is a rare disease. Until now, 11 patients have been reported. Herein, we report a 57-year-old man who had a neck mass that was incidentally found. Aspiration cytology and subsequent needle biopsy of the tumor were performed and suggested papillary thyroid carcinoma. From the resected specimen, however, the patient was finally diagnosed with parathyroid adenoma with prominent lymphocytic infiltrate, characterized by hyperplastic parathyroid cells with nuclear atypia within fibrotic stroma along with numerous lymphocytes forming germinal centers. Some eosinophils and plasma cells were also observed with some histological features highly suggestive of IgG4-related disease (IgG4-RD), including increased IgG4-positive plasma cells and IgG4/IgG-positive plasma cell ratio, storiform-type fibrosis, and obliteratorive phlebitis. It turned out that microfollicular or trabecular architecture and cellular atypia with high expression of HBME-1 observed in the aspiration cytology and needle biopsy had been misinterpreted as a thyroid malignancy. This is the first report describing microscopic features of aspiration cytology and needle biopsy of parathyroid adenoma with prominent lymphocytic infiltrate, warning that it can mimic papillary thyroid carcinoma in biopsy specimens. Furthermore, the IgG4-RD-like features of the present case and previous reports imply that parathyroid adenoma with prominent lymphocytic infiltrate may be a type of IgG4-RD.

Key words: Parathyroid adenoma with prominent lymphocytic infiltrate, Parathyroid adenoma, Parathyroid neoplasms, IgG4-related disease, Papillary thyroid carcinoma

PARATHYROID ADENOMA with prominent lymphocytic infiltrate is a rare disease, characterized by prominent lymphocytic infiltration in the adenomatous parathyroid gland, which has been reported in 11 patients [1-6]. Because of its rarity, clinicopathological and immunohistochemical (IHC) characteristics of the tumor are largely unrevealed. Here we describe a patient with parathyroid adenoma with prominent lymphocytic infiltrate, including its cytomorphicological characteristics in aspiration cytology and needle biopsy for the first time. The tumor showed infiltration-like pattern and diffuse expression of HBME-1 that can be a diagnostic pitfall with malignancy, such as papillary thyroid carcinoma (PTC) on needle biopsy. Furthermore, the tumor exhibited features highly suggestive of IgG4-related disease (IgG4-RD), which implied a close association between parathyroid adenoma with prominent lymphocytic infiltrate and IgG4-RD.

Case Presentation

A 57-year-old man presented a well-demarcated mass in the left thyroid, which was incidentally found during a neck ultrasonography and computed tomography (CT) in 2015 (Fig. 1a, b). Serum thyroid function tests were within normal limits. Fine needle aspiration cytology was carried out, which was diagnosed as atypia of undetermined significance. Needle biopsy was performed and PTC was suggested. In the preoperative work-up, serum calcium and PTH levels were elevated to 12.2 mg/dL.
(normal range: 8.8–10.5 mg/dL) and 252.1 ng/L (normal range: 15–65 ng/L), respectively, indicating primary hyperparathyroidism. Technetium-99m sestamibi SPECT/CT (Fig. 1c) demonstrated high uptake at the lower aspect of the left thyroid; however, it was inconclusive between a parathyroid lesion and PTC, as suggested from the needle biopsy. Consequently, total thyroidectomy with parathyroid exploration was carried out (Fig. 1d).

The cytology specimen showed oncocytic cells occasionally forming microfollicles and some inflammatory cells in the background (Fig. 2a). Nuclei of tumor cells were overlapped and had mild to moderate atypia (Fig. 2b). In the needle biopsy specimen, tumor cells having hyperchromatic nuclei with irregular borders showed infiltrating patterns in the fibrotic stroma (Fig. 2c). In IHC staining, tumor cells expressed HBME-1 in IHC staining (d).

The resected tumor measured $3.9 \times 3.0 \times 2.9$ cm and
was located adjacent to but separated by a fibrotic capsule from the left lower pole of the thyroid (Figs. 1d and 3a). Hyperplastic tumor cells were arranged in a trabecular or microfollicular pattern with the proportional variation of fibrotic stroma, mimicking stromal invasion (Fig. 3b). Neither capsular nor vascular invasion was observed. Tumor cells were diffuse-positive for PTH (Fig. 3c) but negative for TTF-1 or TG (figure not shown) in IHC staining. In addition, lymphocytic infiltration was prominent, forming secondary follicles with mature germinal centers (Fig. 3a, d, e), highlighted by IHC staining for CD3 (Fig. 3d) and CD20 (Fig. 3e). The Ki-67 index was approximately 1% in tumor cells (figure not shown). PD-L1 was expressed mostly in stromal inflammatory cells and in a few tumor cells (1%) (f).

Discussion

Parathyroid adenoma with prominent lymphocytic infiltrate is a rare condition. Including the present case, 12 patients have been reported (Table 1) [1-6]. The median age was 58 years old (range, 29–74) with slight female predominance (male:female = 1:1.4). Some patients (n = 4) suffered from renal colic [1], hypertension [1], duodenal ulcer [3], or osteopenia [4], which were probably associated with hyperparathyroidism [7]. Otherwise, patients were asymptomatic (n = 8). The location of parathyroid adenoma with prominent lymphocytic infiltrate was primarily orthotopic (n = 11) without predilection for sites. Exceptionally, one patient had a heterotopic tumor in the anterior mediastinum (n = 1) [5]. The mean diameter was 1.9 ± 1.1 cm (mean ± standard deviation). Most patients (n = 11) had no history of autoimmune disease, except for one who had ten years of psoriasis [1]. Four patients had concomitant thyroid diseases, including nodular goiter (n = 3) [2, 4] or PTC (n = 1, present). Two patients had received chemotherapy for breast cancer before diagnosis [2, 4].

The histopathologic features of the present patient were compatible to those of the previous reports (Table 1) [1-6]. Numerous inflammatory cells were composed of predominantly lymphocytes, forming germinal cen-
ters, along with some eosinophils and plasma cells. Infiltrating lymphocytes were composed of mixed T- and B-cells (CD3:CD20 = 1.5:1) with a similar CD4-to-CD8 T-cell ratio (figure not shown), which is dissimilar to the predominance of CD4-positive T-cells in Hashimoto thyroiditis [8]. Germinal center architectures were well-preserved. Moreover, the absence of atypical lymphoid cells, lymphoepithelial lesion [6], or in situ hybridization reactivity to Epstein-Barr virus (figure not shown) excluded the possibility of parathyroid lymphoma, a very rare but worrisome disease [9]. PD-1/PD-L1 interaction is an immune-checkpoint that regulates inflammatory reaction [10, 11]. The low PD-L1 expression of tumor cells of parathyroid adenoma with prominent lymphocytic infiltrate was hypothesized to reflect a low level of immune-evasion or immune-tolerance of the tumor cells [10]. In addition, the high PD-L1 expression of stromal lymphocytes was in line with the idea that the immunosuppressive inflammatory cells were ineffective in chronic inflammatory disorders [11].

Thick banding fibrosis, trabecular arrangement of atypical epithelial cells, and marked enlargement of adenoma were distinct features in this case. These features raised the possibility of atypical parathyroid adenoma, an entity intermediate between parathyroid adenoma and carcinoma [12]. In this patient, nevertheless, the absence of mitosis and the low Ki-67 index of tumor cells, which was much lower than that of previous reports (3.9%) on atypical parathyroid adenoma [13], suggested the benign nature of the present case. However, atypical parathyroid adenomas with <1% Ki-67 index have also been reported [14, 15]. Because the malignant potential of parathyroid adenoma with prominent lymphocytic infiltrate is not known, further study is needed. The patient has been regularly followed up for 3 years after surgery without local recurrence or distant metastasis.

Notably, this case mimicked PTC in cytology and in needle biopsy specimens. The microfollicular architecture of cells observed in the aspiration cytology was misinterpreted as thyroid neoplasm, or atypia of unknown significance. Nuclear atypia, which may have been associated with inflammatory reactions, made cytologic diagnosis more challenging because it is rare in parathyroid lesions [16]. In the needle biopsy, the trabecular structure of epithelial cells embedded in the abundant fibrotic stroma and relatively irregular nuclei with oncocytic cytoplasm resembled infiltrating carcinoma. Moreover, IHC staining for HBME-1 was diffuse-positive in tumor cells. Even though HBME-1 is a useful marker in diagnosing thyroid carcinoma, its sensitivity and specificity have been variable among studies and cautions regarding its interpretation should be taken [17-19]. Previously, 11.9% of parathyroid adenomas expressed HBME-1 [14]. Therefore, it is necessary to enlist parathyroid adenoma with prominent lymphocytic infiltrate on the differential diagnoses of PTC in aspiration cytology or needle biopsy, especially when patients have hyperparathyroidism and supportive results on imaging work-ups.

Fig. 4  Inflammatory infiltrate contains lymphocytes, plasma cells, and some eosinophils (a). Storiform-type fibrosis is observed vaguely (b). In a high-power field, >100 plasma cells positive for IgG4 are found (c), which are approximately 40–60% of IgG-positive plasma cells in the serial section (scale bar = 10 μm) (d). Lymphocytes and plasma cells infiltrate into the venous wall that is apparent on elastin staining, inducing obliterative phlebitis (e). Apart from the adenoma, a papillary microcarcinoma was found in the contralateral lobe of the thyroid, which expressed the BRAF V600E mutant protein (f).
Dense infiltration of lymphocytes as well as eosinophils, an increased number of IgG4-positive plasma cells with increased IgG4/IgG-positive plasma cell ratio, together with storiform-type fibrosis and obliterative phlebitis are typical histopathological features of IgG4-RD, a fibroinflammatory disorder involving almost all organs [20]. The number of IgG4-positive plasma cell and its ratio to IgG-positive plasma cell are 10–200/high-power field and >40%, respectively, in IgG4-RD [21]. Clinically, the disease commonly manifests as a mass lesion with or without systemic symptoms [21]. Many distinct inflammatory disorders, for example Riedel thyroiditis, have been revealed to be closely connected to IgG4-RD [21, 22]. Although its involvement in the parathyroid gland has not been reported and supportive clinical information, for example serum IgG4 level, was not evaluated in this patient before the operation, the characteristic histopathological features observed in this patient indicate that the tumor of this patient has the features of IgG4-RD [20]. There was no evidence of disease involvement in other organs on the neck region. The postoperative serum IgG4 level was within the normal range, which might have decreased after the curative resection. Alternatively, it might have been within normal limits at the presentation because serum IgG4 concentration is neither sufficiently sensitive nor specific for IgG4-RD [23]. Moreover, some of previous reports on parathyroid adenoma with prominent lymphocytic infiltrate described stromal fibrosis [1, 4] and infiltration of plasma cells [1-4, 6] that were reminiscent of IgG4-RD, which raises the possibility that parathyroid adenoma with prominent lymphocytic infiltrate is actually parathyroid adenoma with IgG4-RD features. IgG4-RD usually decreases the functions of the involved organs by inducing scar-like fibrosis, e.g. Riedel thyroiditis or autoimmune pancreatitis [22]. However, organ-stimulatory effect of IgG4 was described in a portion of Graves’ disease [24, 25]. Including the present case, five patients with parathyroid adenoma with prominent lymphocytic infiltrate were reported to have hyperparathyroidism (Table 1).

* The patient was taking sodium alendronate for osteopenia

Parathyroid adenoma with IgG4-RD feature
It is possible that IgG4 in the parathyroid glands of these patients acted as a parathyroid-stimulating immunoglobulin on the affected parathyroid gland that would promote the secretion of PTH and the proliferation of parathyroid chief cell. However, given that the other remnant parathyroid glands showed no evidence of hyperplasia in all cases, we should also consider the possibility that certain parathyroid adenomas may expose the neoantigen which provokes the immunologic reactions similar to those of IgG4-RD [26].

To confirm that hypothesis, it should be followed by the retrospective studies with more cases in the future.
