INTRODUCTION

A Jehovah’s Witness (JW) is a member of a Christian denomination that refuses blood transfusion. They believe that the Bible strictly prohibits the transfer of blood or blood products into a person’s body. Therefore, they do not accept transfusions of whole blood (allogeneic and autologous) or its main components (red blood cells, plasma, white blood cells, and platelets) [1-4].

Perioperative blood conservation strategies (BCSs) can be adopted to reduce blood loss and minimize blood transfusion in patients undergoing surgery with a risk of bleeding and in patients who refuse blood transfusion [5,6]. Some JW patients allow the use of blood cell fractions, erythropoietin, acute normovolemic hemodilution, and intraoperative cell salvage, based on personal decision [1-4]. They may also al-

Jehovah’s Witnesses (JWs) refuse allogeneic blood transfusions based on their religious beliefs. Anesthesiologists apply perioperative blood conservation strategies (BCSSs) in patients who refuse allogeneic blood transfusions to prevent significant anemia or bleeding and avoid the need for transfusion. Therefore, we aimed to evaluate whether JW patients could safely undergo various surgeries that have a risk of bleeding without allogeneic transfusion, and compared their outcomes to those of patients allowing blood transfusion. We retrospectively collected data from 59 JW patients (JW group) and 362 non-JW patients (non-JW group) from January 1, 2010 to July 30, 2020. We defined surgeries with a risk of bleeding as open abdominal surgery, open gynecologic surgery, open hip surgery, open knee surgery, and spinal surgery. The primary endpoint was the mortality rate, and the secondary endpoints were the frequency of BCS application and postoperative morbidity. The mortality rate was 0% in the JW group and 3% in the non-JW group (p=0.370). The application of BCS was not significantly different between the groups (p=0.071). Postoperative infection occurred in 8.4% of the non-JW group and in none in the JW group (p=0.013); similarly, the incidence of disseminated intravascular coagulation was higher in the non-JW group (16%) compared to the JW group (3.4%) (p=0.008). JW patients can safely undergo surgeries that have a risk of bleeding without significant mortality and perioperative complications, with comparable outcomes to patients who received blood transfusion.

Keywords: Blood conservation strategy; Jehovah’s Witnesses; Morbidity; Mortality; Transfusion
low transfusion of their own blood by intraoperative cell salvage if the circuit system used remains continuous with their blood vessels at all times [1-4]. BCSs have been effective in the safe performance of bloodless surgeries in patients refusing transfusions, such as in JW patients [7-11]. However, there is still insufficient evidence on the safety of bloodless surgeries, especially in JWs, due to the small sample size of previous studies, including case reports.

Furthermore, there is still a risk for severe anemia requiring blood transfusion due to perioperative blood loss despite the application of BCSs [12]. Unlike in other patients who refuse transfusion, anesthesiologists often face an ethical, clinical, and medicolegal dilemma (whether or not to perform blood transfusion) in the management of perioperative bleeding and intrinsic anemia requiring transfusion in JW patients [13,14]. For this reason, some surgeons and hospitals often avoid accepting JW patients who need surgeries with a high risk of bleeding or complicated surgeries requiring blood transfusion.

In this study, we hypothesized that JW patients could safely undergo various surgeries without allogeneic blood transfusions. Through a review of electronic medical records, we analyzed the applied BCSs, perioperative hematologic changes, and morbidity and mortality in JW patients who underwent various surgeries with a risk of bleeding, and compared their outcomes to those of patients who received blood transfusion.

**MATERIALS AND METHODS**

**Study design and ethical statement**

The Institutional Review Board (IRB) of Chosun University Hospital approved this retrospective study based on a review of electronic medical records (CHOSUN 2020-08-018) on September 10, 2020. The IRB waived the requirement for written informed consent from patients because the data were anonymized before analysis, and this study had no more than minimal risk to the subjects. This study was conducted in accordance with the Declaration of Helsinki of 1964, and all subsequent revisions.

**Study population selection**

We enrolled JW and non-JW patients aged 18-100 years who underwent surgery between January 1, 2010 and July 30, 2020. We excluded patients with preoperative coagulopathy and American Society of Anesthesiologists physical status (ASA-PS) classifications IV and V. We first collected data from 179 JW patients aged 18-100 years who underwent surgery between January 1, 2010 and July 30, 2020 (JW group, Fig. 1). The final list was eventually reduced to 59 JW patients who underwent surgery that have a risk of bleeding (open abdominal surgery, open gynecologic surgery, open hip surgery, open knee surgery, and spinal surgery) of ≥500 mL perioperatively. As a control group, we enrolled non-JW patients who underwent the same surgeries that have a risk of bleeding, performed by the same surgeon during the
same period (non-JW group, Fig. 1). We collected data from 430 non-JW patients, and finally reduced the non-JW group to include 362 patients who underwent surgeries with a risk of ≥ 500 mL of bleeding.

Outcomes

Demographic data

We assessed age, sex, weight, height, body mass index (BMI), ASA-PS, emergency status, classification of surgery, anesthesia duration, hospital stay duration, perioperative input (crystalloid and colloid), and blood loss.

Perioperative BCS

We assessed the use of perioperative antifibrinolytics, iron preparations, other systemic hemostatics, and cell salvage. Moreover, we assessed the anesthesia method, perioperative incidence of hypothermia, and intraoperative methods applied to prevent hypothermia. Hypothermia was defined as a body temperature of ≤36.0°C.

Perioperative transfusions

We assessed the use of packed red blood cells, platelets, fresh frozen plasma, albumin, cryoprecipitate, and blood cell salvage.

Mortality, morbidity, and other complications

We assessed the incidences of death, infection, and disseminated intravascular coagulation (DIC) that occurred during hospitalization. Postoperative infection was defined as surgical wound infection or systemic infection, septicemia, peritonitis, and other infectious complications described in the medical records. DIC was defined as a disease state associated with abnormal prothrombin time (≥ 3 s higher than the reference value) or thrombocytopenia (platelet count <100 × 10^3/mm^3) during the perioperative period, or clinically evident impaired coagulation in the medical records.

Changes in complete blood count, blood coagulation variables, and blood chemistry variables

We assessed the complete blood count (CBC; hemoglobin and platelet counts), coagulation variables (activated partial thromboplastin time [APTT], prothrombin time [PT], and international normalized ratio [INR]), and blood chemistry variables (glucose, blood urea nitrogen [BUN], and serum creatinine [Cr]) preoperatively, postoperatively (within 2 days after the end of surgery), and before discharge.

Analysis

All statistical analyses were performed using IBM SPSS Statistics for Windows (version 26.0; IBM Corp., Armonk, NY, USA). All data are presented as the mean (95% confidence interval) or number (percentage) of patients. The primary endpoint was the mortality rate, and the secondary endpoints were the frequency of BCS application, perioperative morbidity, and changes in hematologic variables.

Continuous variables were analyzed using the t-test, and nominal variables were analyzed using the χ^2 test or Fisher’s exact test, as appropriate. For the analysis of time interval data that passed Mauchly’s sphericity test, we used repeated-measures analysis of variance (ANOVA). For data that did not pass Mauchly’s sphericity test, we used Wilk’s lambda multivariate ANOVA. To compare the groups in a given time interval, the χ^2 test was used. Statistical significance was set at p<0.05.

RESULTS

We enrolled a total of 421 patients (59 JW patients and 362 non-JW patients) after reviewing their electronic medical records (Fig. 1). We excluded 120 from 179 patients in the JW group who underwent surgery without a risk of bleeding (n=117) and had ASA-PS IV and V (n=3). We likewise excluded 68 from 430 patients in the non-JW group who underwent surgery without a risk of bleeding (n=49) and had ASA-PS IV and V (n=19).

Demographic data

Significant differences in age, height, weight, and BMI were not observed, except for a higher number of female patients in the JW group (84.7%) than in the non-JW group (62.4%) (Table 1). The JW group underwent emergent surgeries more frequently (35.6%) than the non-JW group (10.5%) (p<0.001, Table 1). The ASA-PS classification significantly differed between the groups (p=0.001, Table 1). The proportion of patients with ASA-PS I was higher in the JW group (35.6%) than in the non-JW group (14.9%), whereas the pro-
The various surgeries performed showed significant differences between groups (p<0.001, Table 2). In the JW group, spinal surgery was the most common surgery performed, followed by open gynecologic surgery, open knee surgery, and open abdominal surgery. In the non-JW group, open hip surgery was the most common surgery performed, followed by spinal surgery, open gynecologic surgery, open knee surgery, and open abdominal surgery.

The duration of anesthesia was shorter in the JW group than in the non-JW group (p<0.001, Table 3). Perioperative (intraoperative and postoperative) blood loss was lower in the JW group than in the non-JW group (p<0.001, Table 3). The infused crystalloid volume intraoperatively was lower in the JW group than in the non-JW group (p<0.001, Table 3). The frequency of perioperative colloid infusion was also lower in the JW group (16.9%) than in the non-JW group (35.1%) (p=0.006, Table 3).

The overall rate of perioperative transfusion was significantly different between the JW (15.3%) and the non-JW (74.3%) groups (p<0.001, Table 3). The JW group did not receive any packed red blood cells, platelets, fresh frozen plasma, or cryoprecipitate. Albumin was administered to 4 (6.8%) patients in the JW group and 83 (22.9%) patients in the non-JW group (p=0.003). Autologous blood transfusion after cell salvage was administered to 6 (10.2%) patients in the JW group and 31 (8.6%) patients in the non-JW group (p=0.686).

Table 1. Demographic data (n=421)

|                          | JW group (n=59) | Non-JW group (n=362) | p-value |
|--------------------------|-----------------|----------------------|---------|
| Age (y)                  | 62.8 (68.4)     | 65 (66.5)            | 0.317   |
| Female sex               | 50 (84.7)       | 226 (62.4)           | 0.001*  |
| Weight (kg)              | 60.5 (57.8)     | 63.4 (61.5)          | 0.230   |
| Height (cm)              | 156.7 (154.3)   | 157.6 (155.9)        | 0.688   |
| BMI (kg/m²)              | 24.6 (23.68)    | 33.2 (26.32)         | 0.331   |
| ASA-PS (1/II/III)        | 21/33/5 (35.6/55.9/8.5) | 54/206/102 (14.9/56.9/28.2) | <0.001* |
| Emergency (no/yes)       | 38/21 (64.4/35.6) | 324/38 (89.5/10.5)   | <0.001* |

Values are expressed as mean (95% confidence interval) or number (percentage) of patients.
JW: Jehovah’s Witness, BMI: body mass index, ASA-PS: American Society of Anesthesiologists physical status.
*p<0.05 was considered to indicate statistical significance.

Table 2. Classification of surgeries (n=421)

|                          | JW group (n=59) | Non-JW group (n=362) | p-value |
|--------------------------|-----------------|----------------------|---------|
| Open abdominal surgery   | 5 (8.5)         | 50 (13.8)            | <0.001* |
| Open gynecologic surgery | 15 (25.4)       | 55 (15.2)            |         |
| Open hip surgery         | 5 (8.5)         | 118 (32.6)           |         |
| Open knee surgery        | 14 (23.7)       | 50 (13.8)            |         |
| Spinal surgery, 1 level  | 10 (16.9)       | 22 (6.1)             |         |
| Spinal surgery, 2 levels | 6 (10.2)        | 16 (4.4)             |         |
| Spinal surgery, >3 levels| 4 (6.8)         | 51 (14.1)            |         |

JW: Jehovah’s Witness.
*p<0.05 was considered to indicate statistical significance.

portion of those with ASA-PS III was higher in the non-JW group (28.2%) than in the JW group (8.5%) (Table 1).

The duration of anesthesia was shorter in the JW group than in the non-JW group (p<0.001, Table 2). In the JW group, spinal surgery was the most common surgery performed, followed by open gynecologic surgery, open knee surgery, open hip surgery, and open abdominal surgery. In the non-JW group, open hip surgery was the most common surgery performed, followed by spinal surgery, open gynecologic surgery, open knee surgery, and open abdominal surgery.

The duration of anesthesia was shorter in the JW group than in the non-JW group (p<0.001, Table 3). Perioperative (intraoperative and postoperative) blood loss was lower in the JW group than in the non-JW group (p<0.001, Table 3). The infused crystalloid volume intraoperatively was lower in the JW group than in the non-JW group (p<0.001, Table 3). The frequency of perioperative colloid infusion was also lower in the JW group (16.9%) than in the non-JW group (35.1%) (p=0.006, Table 3).

The overall rate of perioperative transfusion was significantly different between the JW (15.3%) and the non-JW (74.3%) groups (p<0.001, Table 3). The JW group did not receive any packed red blood cells, platelets, fresh frozen plasma, or cryoprecipitate. Albumin was administered to 4 (6.8%) patients in the JW group and 83 (22.9%) patients in the non-JW group (p=0.003). Autologous blood transfusion after cell salvage was administered to 6 (10.2%) patients in the JW group and 31 (8.6%) patients in the non-JW group (p=0.686).
Mortality, morbidity, and other complications
The mortality rate in the JW group was 0%, which was lower than that in the non-JW group (3%), but was not statistically significant (p=0.370, Table 4). Massive bleeding occurred in 3.4% and 11.8% of patients in the JW and the non-JW groups, respectively, but the difference was also not statistically significant (p=0.064, Table 4). There were no postoperative infections in the JW group, compared to 8.4% in the non-JW group (p=0.013, Table 4). Early discontinuation of surgery was not done in the JW group but occurred in 0.9% of patients in the non-JW group (p=1.000, Table 4). The incidence of DIC was higher in the non-JW group (16%) than in the JW group (3.4%) (p=0.008, Table 4). Hospital stay was shorter in the JW group than in the non-JW group (p<0.001, Table 4).

Changes in CBC, blood coagulation variables, and blood chemistry variables
Changes in CBC
The perioperative hemoglobin level was not significantly different between the groups (p=0.075, Table 5). However, the hemoglobin level at each time point was higher in the JW group than in the non-JW group (p≤0.006, Table 5). The incidence of hemoglobin levels <10 g/dL was lower in the JW group than in the non-JW group throughout the perioperative period (p≤0.005, Table 5).

The perioperative platelet count was significantly different between the groups (p=0.018, Table 5). The postoperative platelet count was higher in the JW group than in the non-JW group (p=0.028, Table 5), whereas the preoperative and discharge platelet counts were not significantly different between the groups. The incidence of postoperative platelet count <150×10^3/mm^3 was lower in the JW group (5.1%) than in the non-JW group (20.4%, p=0.005); however, the incidence of low platelet count before surgery and at discharge was not significantly different (Table 5).

Changes in blood coagulation variables
Perioperative APTT, PT, and INR were higher in the non-JW group than in the JW group (p<0.001, Table 6), although preoperatively, there was no significant difference between the groups in these variables. The incidences of prolonged PT (≥12.6 s) and elevated INR (≥1.28) were higher in the non-JW group than in the JW group at the end of surgery (p<0.001) and before discharge (p<0.001, Table 6). However, the incidence of prolonged APTT (≥45 s) was not significantly different between the groups throughout the perioperative period.

Changes in blood chemistry variables
Perioperative blood chemistry variables were not significantly different between the groups (Table 7). At each measurement point, the perioperative blood glucose, BUN, and Cr levels also did not show significant differences between
Table 6. Perioperative coagulation variables (n=421)

the groups, except for the higher preoperative glucose level in the non-JW group than in the JW group (Table 7).

The incidences of perioperatively elevated blood glucose, BUN, and Cr levels were not significantly different, although there was a higher proportion of patients with abnormal postoperative glucose levels at the end of surgery in the JW group (78%) than in the non-JW group (61.9%) (p=0.017, Table 7).

Perioperative BCS
Iron preparations and other systemic hemostatics were more frequently used in the JW group than in the non-JW group (p<0.001, Table 8); however, antifibrinolytics were less frequently used in the JW group (p=0.007, Table 8). The use of cell salvage was not significantly different between the groups (Table 8). None of the patients received other BCSs, such as administration of erythropoietin and prothrombin complex concentrate.

The anesthesia methods did not show significant differences between the groups (p=0.709, Table 8). In the JW group, balanced anesthesia was the preferred method, followed by total intravenous anesthesia, inhaled anesthesia, and neuroaxial anesthesia. In the non-JW group, balanced anesthesia was also the preferred method, followed by inhaled anesthesia, total intravenous anesthesia, and neuroaxial anesthesia.

The incidences of intraoperative and postoperative hypothermia were significantly different between the groups (p=0.013 and p=0.003, respectively; Table 8). All JW patients
Bloodless surgery in Jehovah’s Witness patients

DISCUSSION

This study is meaningful in that it analyzed the outcomes of perioperative management of Korean JW patients undergoing bloodless surgeries. The results of this study showed that most JW patients safely underwent surgery without blood transfusions and without developing significant hematologic abnormalities, compared to patients who received blood transfusion under standard transfusion protocols.

Mortality, morbidity, and other complications

Preoperative correction of anemia is essential, as decreased preoperative hemoglobin levels are associated with increased morbidity and mortality [15]. Therefore, allogeneic blood and blood derivatives are usually transfused to compensate for significant intraoperative blood loss. However, allogeneic blood transfusion can lead to perioperative coagulopathy or even DIC, which can result in postoperative bleeding, renal failure, increased risk of infection, prolonged hospital stay, and increased postoperative morbidity and mortality, independent of patient comorbidities and preoperative hemoglobin levels [16-18].

JW patients who received perioperative BCSs showed similar or better outcomes compared to patients who received blood transfusion [19-22]. In open knee surgeries, the postoperative complication rate was not significantly different between the JW (3.9%) and non-JW (3.2%) groups [20]. In JW patients who underwent bloodless emergency laparotomy with hemorrhagic shock, mortality was lower in the JW group (12%) than in the group that received blood transfusion (15.6%) [21]. They also showed that the infectious mortality rate was lower (30% vs. 40%) and the DIC incidence was lower (0.0% vs. 4.4%) in JW patients than in patients who received allogeneic blood transfusion [21]. In the study by Kim et al. [22], the perioperative Cr level, as an indicator of renal injury, was not significantly different between the groups.

Postoperative anemia-related mortality was relatively uncommon in JW patients, and overall mortality was lower in patients who refused (0%) than in those who received blood transfusion (3.6%) [19,20,23]. Frank et al. [19] reported that the mortality rate was not significantly different between groups, although the incidence of hemoglobin nadir <5 g/dL was higher in JW patients (4.3%) than in patients who received blood transfusion (0.2%). The hemoglobin levels of JW patients who received BCSs did not significantly differ from those of non-JW patients at 1 d postoperatively [20]. De Bellis et al. [24] reported that the lowest hemoglobin level was 7.1 g/dL with a median decrement of 2.8 g/dL (range 0-6.9 g/dL), and no patient required blood transfusion or died within 3 months after surgery among JW patients who

Table 8. Perioperative blood conservation strategies (n=421)

| Prevention methods (yes/no) | JW group (n=59) | Non-JW group (n=362) | p-value |
|-----------------------------|-----------------|----------------------|---------|
| Overall                     | 23/36 (39.6%)   | 243/311 (79.7%)      | <0.001* |
| Forced-air warming           | 23/36 (39.6%)   | 236/93 (70.8%)       | <0.001* |
| IV fluid warming            | 3/56 (5.3%)     | 61/246 (22.1%)       | 0.006*  |
| Passive warming              | 2/57 (3.4%)     | 23/281 (8.2%)        | 0.398   |

experienced mild hypothermia (35.5°C<temperature≤36.0°C), whereas normal body temperature and mild hypothermia were observed in 10% and 90% of patients receiving blood transfusion, respectively.

Protocols for preventing hypothermia, which include forced-air warming (p<0.001) and intravenous fluid warming (p=0.006), were more frequently applied in the non-JW group than in the JW group (p<0.001, Table 8).
underwent major abdominal surgeries. Furthermore, propensity-matched studies showed lower morbidity and mortality rates in patients who underwent bloodless surgeries [19,25]. However, it should be considered that postoperative hemoglobin <5.0 g/dL has been shown to increase mortality in JW patients [12,26] and specific surgeries with risks of catastrophic hemorrhage also increase the mortality risk in patients undergoing bloodless surgeries [27].

This study showed decreased perioperative blood loss and lower incidences of postoperative infection, coagulopathy, and DIC in the JW group than in the non-JW group, whereas mortality, massive bleeding, and renal insufficiency were not significantly different between the groups. It was assumed that the non-JW group liberally received perioperative allogeneic transfusion and fluid administration, causing abnormal coagulation profiles and increased postoperative bleeding, eventually increasing the risk for postoperative infection, DIC, and prolonged hospital stay.

Perioperative BCS

Various perioperative BCSs can be used to minimize blood loss, optimize anemia tolerance, enhance hemoglobin and red blood cell production, correct coagulation defects, and promote hemostasis. These BCSs include the administration of erythropoietin, prothrombin complex concentrate, oral or intravenous iron preparations, and antifibrinolytics; preoperative autologous donation; acute normovolemic hemodilution; autologous blood transfusion after cell salvage; and use of various anesthetic techniques, such as intraoperative induction of mild hypothermia and application of permissive hypotension [14-16,28-30]. Many studies have shown that patients who refuse blood transfusion, such as JW, can safely undergo surgery with the application of aggressive BCSs [16,31-33].

The present study also showed that BCSs were more frequently applied in JW patients (61%), who were able to undergo surgery without allogeneic blood transfusion in a safer manner than patients who received blood transfusion (48.3%). In addition, the perioperative application of BCSs was effective in achieving hemoglobin nadirs and outcomes in JW patients similar to those in patients who received transfusion [16].

Perioperative management with medicine

This study showed that hemocoagulase, which is classified as a group of other systemic hemostatics, was the most commonly applied BCS (37.3%) in JW patients, followed by iron preparations (15.3%), antifibrinolytics (10.2%), and cell salvage (10.2%). In contrast, in non-JW patients, antifibrinolytics (26.2%) were the most commonly applied BCS. At our hospital, we could not use erythropoietin because of the constraints of health insurance schemes. Therefore, we preferred using antifibrinolytics, oral or intravenous iron preparations, and other systemic hemostatics. Although erythropoietin is an effective alternative to blood transfusion, it has another limitation of taking a long time (4 weeks) to promote sufficient erythropoiesis (3 days for erythropoiesis, 7 days for 1 unit of blood, and 28 days for 5 units of blood) [31]. Therefore, erythropoietin may be ineffective in overcoming perioperative blood loss if not administered early enough.

Anesthetic techniques

Permissive or induced hypotension (systolic blood pressure of 80–90 mmHg, mean arterial pressure of 50–65 mmHg, or a 30% reduction in the mean arterial pressure at baseline) can reduce perioperative blood loss in JW patients [4,34,35]. Effective permissive hypotension can be achieved using pharmacological agents alone or in combination with inhaled anesthetics, sodium nitroprusside, nitroglycerin, remifentanil, calcium channel blockers, β-blockers, and agents used in neuroaxial anesthesia [36]. Balanced anesthesia, total intravenous anesthesia, and neuroaxial anesthesia are preferable anesthetic methods in JW patients, considering the lower toxicity, safer recovery, and natural hypotensive effect of the anesthetic drugs [36,37]. Nwosu [37] documented that anesthesia with permissive hypotension was useful in reducing surgical blood loss and improving surgical site visibility while reducing the surgical time in selected cases, such as in patients undergoing spinal surgery or total hip surgery [16,31]. This study also showed that general anesthesia with opioids and neuroaxial anesthesia was preferred, although we did not investigate whether permissive hypotension was performed.

Induction of mild to moderate hypothermia has also been successfully used as a BCS; however, hypothermia below 35°C should be avoided to prevent coagulopathy and blood loss [14]. Mild intraoperative hypothermia (between
35.5°C and 36.0°C) was observed in all JW patients and in 91.4% of non-JW patients in this study.

Transfusions

Although JWs refuse allogeneic blood transfusion, some may allow the prevention or control of perioperative anemia with acute normovolemic hemodilution or blood cell salvage, based on personal decision [1-4,30]. However, we could not perform acute normovolemic hemodilution because of the policy restrictions of blood banks and technical difficulties in our hospital. Therefore, we only applied perioperative autologous blood cell salvage to minimize the need for allogeneic transfusion as an alternative technique. Although not routinely performed, the use of blood that remains in continuity with the patient’s circulation can be safely accepted by JWs on a per-patient basis [38-40]. If possible, blood salvage is recommended as a backup measure in patients undergoing surgeries with a risk of moderate or low blood loss [19]. Blood salvage was applied in 10.2% of JW patients and 8.6% of non-JW patients in this study.

Surgical techniques

When performing complex and lengthy surgeries in JW patients, surgeons should consider staged operations or techniques that can reduce the risk of perioperative bleeding and transfusion [14,15]. The JW patients enrolled in this study underwent less complex surgeries with a short expected operative time, and none of them required a staged operation.

Study limitations

This study has several limitations, warranting cautious interpretation of our findings. First, the retrospective analysis may have influenced the results of this study. Second, the single-center design and the small sample size of the JW group limit the generalization of our results. Third, we included many different types of surgeries, which may have resulted in unfair comparisons. Finally, we did not perform propensity matching to control for various biases. As a result of the uncontrolled biases, various types of surgeries were included in the analysis of this study at different frequencies between the groups, which may have resulted in significant differences in anesthetic duration, perioperative fluid infusion amounts, and incidence of perioperative hypothermia and DIC.

In conclusion, most JW patients can safely undergo surgeries that have a risk of bleeding without blood transfusions, similar to patients who are given blood transfusion. This was achieved through physicians’ efforts to reduce or prevent perioperative bleeding by applying various perioperative BCs. Despite the limitations of our retrospective study and the need for further studies to confirm our results and conclusions, the present findings are useful in that they support existing findings and contribute to updating the information on the perioperative outcomes of JW patients. In addition, this study adds to the evidence that perioperative blood transfusion is associated with increased mortality and morbidity after surgery.

ACKNOWLEDGEMENTS

This study was supported by a research fund from Chosun University Hospital (Donggu, Gwangju, Republic of Korea), 2019. The Chosun University Hospital had no role in the design or conduct of the study; collection, management, analysis, or interpretation of the data; and preparation, review, or approval of the manuscript.
