The intersection between the fields of machine learning and quantum information processing is proving to be a fruitful field for the discovery of new quantum algorithms, which potentially offer an exponential speed-up over their classical counterparts. However, many such algorithms require the ability to produce states proportional to vectors stored in quantum memory. Even given access to quantum databases which store exponentially long vectors, the construction of which is considered a one-off overhead, it has been argued that the cost of preparing such amplitude-encoded states may offset any exponential quantum advantage. Here we argue that specifically in the context of classical machine learning applications it suffices to prepare a state close to the ideal state only in the ∞-norm, and that this can be achieved with only a constant number of memory queries.

In recent years, machine learning has emerged as a rich area for quantum algorithms, particularly in the context of quantum machine learning (QML). One significant barrier to the QRAM approach to state preparation is the probability of projecting onto the correct subspace in the final step, which is given by $D^{-1} \sum_{i} |x_i|^2$. When the entries of $x$ are of similar magnitude, $|x\rangle$ can be prepared using constant queries. However, in the case where a few entries are much larger than the rest, the lower bounds on unordered search imply that the corresponding state requires $\Omega(\sqrt{D})$ QRAM queries. This argument can be extended to the case where it is only necessary to prepare any $|x'\rangle$ such that $|x' - x|_2$ is sufficiently small.

However, note that data processing in machine learning always implicitly assumes robustness with respect to the ∞-norm induced distance, which measures just the largest entry-wise perturbation. Specifically, any digital data processing with floating-point arithmetic only makes sense if the overall results of such a computation maintain its validity when the features of the input vector had been perturbed below the machine precision. This is also practically reasonable, since real world data comes from measurements of finite precision. As such, the corresponding constraint is only that $|x' - x|_\infty \leq \epsilon$, rather than requiring closeness in the 2-norm.

One significant barrier to the QRAM approach to state preparation is the probability of projecting onto the correct subspace in the final step, which is given by $D^{-1} \sum_{i} |x_i|^2$. When the entries of $x$ are of similar magnitude, $|x\rangle$ can be prepared using constant queries. However, in the case where a few entries are much larger than the rest, the lower bounds on unordered search imply that the corresponding state requires $\Omega(\sqrt{D})$ QRAM queries. This argument can be extended to the case where it is only necessary to prepare any $|x'\rangle$ such that $|x' - x|_2$ is sufficiently small.

However, note that data processing in machine learning always implicitly assumes robustness with respect to the ∞-norm induced distance, which measures just the largest entry-wise perturbation. Specifically, any digital data processing with floating-point arithmetic only makes sense if the overall results of such a computation maintain its validity when the features of the input vector had been perturbed below the machine precision. This is also practically reasonable, since real world data comes from measurements of finite precision. As such, the corresponding constraint is only that $|x' - x|_\infty \leq \epsilon$, rather than requiring closeness in the 2-norm.
The tolerance against small ∞-norm perturbations allows us to work with the vector entries $x'_i$ which are half-integer multiples of the base precision $\epsilon$. Such that $x'$ is chosen to be the closest representable vector to $x$ (as shown in Figure 1), which satisfies $|x' - x|_{\infty} \leq \frac{\epsilon}{2}$ and the distance from the true value of the data is less than $\epsilon$. This offset rounding can be implemented in the loading of the QRAM, or effectively realised at the controlled rotation stage, as discussed earlier. The aforementioned robustness requirement in data processing guarantees the analysis of results are insensitive to such offset rounding. The key benefit in using the offset rounding is that, since the exact representation of 0 is not included in this offset rounding convention, the probability of the final projection step succeeding is at worst $\frac{\epsilon^2}{4}$, and hence independent of $D$. This success probability can be further improved to $O(\epsilon)$ using fixed-point quantum amplitude amplification \[13\].

In the cases where a systematic perturbation of data-vectors, by utilizing, say, a positive sign offset ($+\epsilon/2$) to data-points is undesirable, one can opt for a near-white noise offset using either a suitable pseudo-random number generator seeded by the memory location being queried or by adding data random data stored elsewhere in QRAM. Furthermore, while $\epsilon$ need not be on the order of machine precision, since any $\epsilon$ which is small compared to accuracy to which the input data is known will lead to negligible error, and hence low precision data will have a more efficient loading procedure then high precision data. Critically, however, the number of QRAM queries necessary to successfully prepare the state always has an upper bound that is independent from the database size.

In summary, any application which is robust under small ∞-norm perturbations allows for efficient state preparation. This suggests that the caveat related to state preparation raised by Aaronson \[9\] can generally be overcome in the context of machine learning, due to the natural robustness assumption. This feature is, however, not necessarily shared by computational physics, or other numerical mathematics applications.
